APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Today's applications are required to be highly responsive and always online. To achieve low latency and high availability, instances of these applications need to be deployed in datacenters that are close to their users. Applications need to respond in real time to large changes in usage at peak hours, store ever increasing volumes of data, and make this data available to users in milliseconds.

Azure Cosmos DB is a fully managed NoSQL database for modern app development. Single-digit millisecond response times, and automatic and instant scalability, guarantee speed at any scale. Business continuity is assured with SLA-backed availability and enterprise-grade security. App development is faster and more productive thanks to turnkey multi-master data distribution anywhere in the world, open source APIs and SDKs for popular languages. As a fully managed service, Azure Cosmos DB takes database administration off your hands with automatic management, updates and patching. It also handles capacity management with cost-effective serverless and automatic scaling options that respond to application needs to match capacity with demand.

You can Try Azure Cosmos DB for Free without an Azure subscription, free of charge and commitments or use the Azure Cosmos DB free tier to get an account with the first 400 RU/s and 5 GB of storage free.

Try Azure Cosmos DB for Free

Key Benefits

Guaranteed speed at any scale

Gain unparalleled SLA-backed speed and throughput, fast global access, and instant elasticity.

- Real-time access with fast read and write latencies globally, and throughput and consistency all backed by SLAs
- Multi-region writes and data distribution to any Azure region with the click of a button.
- Independently and elastically scale storage and throughput across any Azure region – even during unpredictable traffic bursts – for unlimited scale worldwide.

Simplified application development

Build fast with open source APIs, multiple SDKs, schemaless data and no-ETL analytics over operational data.

- Deeply integrated with key Azure services used in modern (cloud-native) app development including Azure Functions, IoT Hub, AKS (Azure Kubernetes Service), App Service, and more.
- Choose from multiple database APIs including the native Core (SQL) API, API for MongoDB, Cassandra API, Gremlin API, and Table API.
- Build apps on Core (SQL) API using the languages of your choice with SDKs for .NET, Java, Node.js and Python. Or your choice of drivers for any of the other database APIs.
- Run no-ETL analytics over the near-real time operational data stored in Azure Cosmos DB with Azure Synapse Analytics.
- Change feed makes it easy to track and manage changes to database containers and create triggered events with Azure Functions.
- Azure Cosmos DB's schema-less service automatically indexes all your data, regardless of the data model, to delivery blazing fast queries.

Mission-critical ready

Guarantee business continuity, 99.999% availability, and enterprise-level security for every application.

- Azure Cosmos DB offers a comprehensive suite of SLAs including industry-leading availability worldwide.
- Easily distribute data to any Azure region with automatic data replication. Enjoy zero downtime with multi-region writes or RPO 0 when using Strong consistency.
- Enjoy enterprise-grade encryption-at-rest with self-managed keys.
- Azure role-based access control keeps your data safe and offers fine-tuned control.

Fully managed and cost-effective

End-to-end database management, with serverless and automatic scaling matching your application and TCO needs

- Fully-managed database service. Automatic, no touch, maintenance, patching, and updates, saving developers time and money.
- Cost-effective options for unpredictable or sporadic workloads of any size or scale, enabling developers to get started easily without having to plan or manage capacity.
- Serverless model offers spiky workloads automatic and responsive service to manage traffic bursts on demand.
- Autoscale provisioned throughput automatically and instantly scales capacity for unpredictable workloads, while maintaining SLAs.

Solutions that benefit from Azure Cosmos DB

Any web, mobile, gaming, and IoT application that needs to handle massive amounts of data, reads, and writes at a global scale with near-real response times for a variety of data will benefit from Cosmos DB's guaranteed high availability, high throughput, low latency, and tunable consistency. Learn about how Azure Cosmos DB can be used to build IoT and telematics, retail and marketing, gaming and web and mobile applications.

Understanding the differences between NoSQL and relational databases

11/2/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

This article will enumerate some of the key benefits of NoSQL databases over relational databases. We will also discuss some of the challenges in working with NoSQL. For an in-depth look at the different data stores that exist, have a look at our article on choosing the right data store.

High throughput

One of the most obvious challenges when maintaining a relational database system is that most relational engines apply locks and latches to enforce strict ACID semantics. This approach has benefits in terms of ensuring a consistent data state within the database. However, there are heavy trade-offs with respect to concurrency, latency, and availability. Due to these fundamental architectural restrictions, high transactional volumes can result in the need to manually shard data. Implementing manual sharding can be a time consuming and painful exercise.

In these scenarios, distributed databases can offer a more scalable solution. However, maintenance can still be a costly and time-consuming exercise. Administrators may have to do extra work to ensure that the distributed nature of the system is transparent. They may also have to account for the "disconnected" nature of the database.

Azure Cosmos DB simplifies these challenges, by being deployed worldwide across all Azure regions. Partition ranges are capable of being dynamically subdivided to seamlessly grow the database in line with the application, while simultaneously maintaining high availability. Fine-grained multi-tenancy and tightly controlled, cloud-native resource governance facilitates astonishing latency guarantees and predictable performance. Partitioning is fully managed, so administrators need not have to write code or manage partitions.

If your transactional volumes are reaching extreme levels, such as many thousands of transactions per second, you should consider a distributed NoSQL database. Consider Azure Cosmos DB for maximum efficiency, ease of maintenance, and reduced total cost of ownership.

Hierarchical data

There are a significant number of use cases where transactions in the database can contain many parent-child relationships. These relationships can grow significantly over time, and prove difficult to manage. Forms of hierarchical databases did emerge during the 1980s, but were not popular due to inefficiency in storage. They also lost traction as Ted Codd's relational model became the de facto standard used by virtually all mainstream database management systems.

However, today the popularity of document-style databases has grown significantly. These databases might be considered a reinventing of the hierarchical database paradigm, now uninhibited by concerns around the cost of storing data on disk. As a result, maintaining many complex parent-child entity relationships in a relational database could now be considered an anti-pattern compared to modern document-oriented approaches.

The emergence of object oriented design, and the impedance mismatch that arises when combining it with relational models, also highlights an anti-pattern in relational databases for certain use cases. Hidden but often significant maintenance costs can arise as a result. Although ORM approaches have evolved to partly mitigate this, document-oriented databases nonetheless coalesce much better with object-oriented approaches. With this approach, developers are not forced to be committed to ORM drivers, or bespoke language specific OO Database engines. If your data contains many parent-child relationships and deep levels of hierarchy, you may want to consider using a NoSQL document database such as the Azure Cosmos DB SQL API.

Complex networks and relationships

Ironically, given their name, relational databases present a less than optimal solution for modeling deep and complex relationships. The reason for this is that relationships between entities do not actually exist in a relational database. They need to be computed at runtime, with complex relationships requiring cartesian joins in order to allow mapping using queries. As a result, operations become exponentially more expensive in terms of computation as relationships increase. In some cases, a relational database attempting to manage such entities will become unusable.

Various forms of "Network" databases did emerge during the time that relational databases emerged, but as with hierarchical databases, these systems struggled to gain popularity. Slow adoption was due to a lack of use cases at the time, and storage inefficiencies. Today, graph database engines could be considered a re-emergence of the network database paradigm. The key benefit with these systems is that relationships are stored as "first class citizens" within the database. Thus, traversing relationships can be done in constant time, rather than increasing in time complexity with each new join or cross product.

If you are maintaining a complex network of relationships in your database, you may want to consider a graph

database such as the Azure Cosmos DB Gremlin API for managing this data.

Azure Cosmos DB is a multi-model database service, which offers an API projection for all the major NoSQL model types; Column-family, Document, Graph, and Key-Value. The Gremlin (graph) and SQL (Core) Document API layers are fully interoperable. This has benefits for switching between different models at the programmability level. Graph stores can be queried in terms of both complex network traversals as well as transactions modeled as document records in the same store.

Fluid schema

Another particular characteristic of relational databases is that schemas are required to be defined at design time. This has benefits in terms of referential integrity and conformity of data. However, it can also be restrictive as the application grows. Responding to changes in the schema across logically separate models sharing the same table or database definition can become complex over time. Such use cases often benefit from the schema being devolved to the application to manage on a per record basis. This requires the database to be "schema agnostic" and allow records to be "self-describing" in terms of the data contained within them.

If you are managing data whose structures are constantly changing at a high rate, particularly if transactions can come from external sources where it is difficult to enforce conformity across the database, you may want to consider a more schema-agnostic approach using a managed NoSQL database service like Azure Cosmos DB.

Microservices

The microservices pattern has grown significantly in recent years. This pattern has its roots in Service-Oriented Architecture. The de-facto standard for data transmission in these modern microservices architectures is JSON, which also happens to be the storage medium for the vast majority of document-oriented NoSQL Databases. This makes NoSQL document stores a much more seamless fit for both the persistence and synchronization (using event sourcing patterns) across complex Microservice implementations. More traditional relational databases can be much more complex to maintain in these architectures. This is due to the greater amount of transformation required for both state and synchronization across APIs. Azure Cosmos DB in particular has a number of features that make it an even more seamless fit for JSON-based Microservices Architectures than many NoSQL databases:

- a choice of pure JSON data types
- a JavaScript engine and query API built into the database.
- a state-of-the-art change feed which clients can subscribe to in order to get notified of modifications to a

container.

Some challenges with NoSQL databases

Although there are some clear advantages when implementing NoSQL databases, there are also some challenges that you may want to take into consideration. These may not be present to the same degree when working with the relational model:

- transactions with many relations pointing to the same entity.
- transactions requiring strong consistency across the entire dataset.

Looking at the first challenge, the rule-of-thumb in NoSQL databases is generally denormalization, which as articulated earlier, produces more efficient reads in a distributed system. However, there are some design challenges that come into play with this approach. Let's take an example of a product that's related to one category and multiple tags:

A best practice approach in a NoSQL document database would be to denormalize the category name and tag names directly in a "product document". However, in order to keep categories, tags, and products in sync, the design options to facilitate this have added maintenance complexity, because the data is duplicated across multiple records in the product, rather than being a simple update in a "one-to-many" relationship, and a join to retrieve the data.

The trade-off is that reads are more efficient in the denormalized record, and become increasingly more efficient as the number of conceptually joined entities increases. However, just as the read efficiency increases with increasing numbers of joined entities in a denormalize record, so too does the maintenance complexity of keeping entities in sync. One way of mitigating this trade-off is to create a hybrid data model.

While there is more flexibility available in NoSQL databases to deal with these trade-offs, increased flexibility can also produce more design decisions. Consult our article how to model and partition data on Azure Cosmos DB using a real-world example, which includes an approach for keeping denormalized user data in sync where users not only sit in different partitions, but in different containers.

With respect to strong consistency, it is rare that this will be required across the entire data set. However, in cases where this is necessary, it can be a challenge in distributed databases. To ensure strong consistency, data needs to be synchronized across all replicas and regions before allowing clients to read it. This can increase the latency of reads.

Again, Azure Cosmos DB offers more flexibility than relational databases for the various trade-offs that are relevant here, but for small scale implementations, this approach may add more design considerations. Consult our article on Consistency, availability, and performance tradeoffs for more detail on this topic.

Azure Cosmos DB resource model

12/4/2020 • 9 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB is a fully managed platform-as-a-service (PaaS). To begin using Azure Cosmos DB, you should initially create an Azure Cosmos account in your Azure subscription and databases, containers, items under it. This article describes the Azure Cosmos DB resource model and different entities in the resource model hierarchy.

The Azure Cosmos account is the fundamental unit of global distribution and high availability. Your Azure Cosmos account contains a unique DNS name and you can manage an account by using Azure portal, Azure CLI or by using different language-specific SDKs. For more information, see how to manage your Azure Cosmos account. For globally distributing your data and throughput across multiple Azure regions, you can add and remove Azure regions to your account at any time. You can configure your account to have either a single region or multiple write regions. For more information, see how to add and remove Azure regions to your account. You can configure the default consistency level on an account.

Elements in an Azure Cosmos account

Azure Cosmos container is the fundamental unit of scalability. You can virtually have an unlimited provisioned throughput (RU/s) and storage on a container. Azure Cosmos DB transparently partitions your container using the logical partition key that you specify in order to elastically scale your provisioned throughput and storage.

Currently, you can create a maximum of 50 Azure Cosmos accounts under an Azure subscription (this is a soft limit that can be increased via support request). A single Azure Cosmos account can virtually manage unlimited amount of data and provisioned throughput. To manage your data and provisioned throughput, you can create one or more Azure Cosmos databases under your account and within that database, you can create one or more containers. The following image shows the hierarchy of elements in an Azure Cosmos account:

After you create an account under your Azure subscription, you can manage the data in your account by

creating databases, containers, and items.

The following image shows the hierarchy of different entities in an Azure Cosmos DB account:

Azure Cosmos databases

You can create one or multiple Azure Cosmos databases under your account. A database is analogous to a namespace. A database is the unit of management for a set of Azure Cosmos containers. The following table shows how a database is mapped to various API-specific entities:

AZURE COSMOS ENTITY	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Azure Cosmos database	Database	Keyspace	Database	Database	NA

> **NOTE**
> With Table API accounts, when you create your first table, a default database is automatically created in your Azure Cosmos account.

Operations on an Azure Cosmos database

You can interact with an Azure Cosmos database with Azure Cosmos APIs as described in the following table:

OPERATION	AZURE CLI	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Enumerate all databases	Yes	Yes	Yes (database is mapped to a keyspace)	Yes	NA	NA
Read database	Yes	Yes	Yes (database is mapped to a keyspace)	Yes	NA	NA
Create new database	Yes	Yes	Yes (database is mapped to a keyspace)	Yes	NA	NA

OPERATION	AZURE CLI	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Update database	Yes	Yes	Yes (database is mapped to a keyspace)	Yes	NA	NA

Azure Cosmos containers

An Azure Cosmos container is the unit of scalability both for provisioned throughput and storage. A container is horizontally partitioned and then replicated across multiple regions. The items that you add to the container are automatically grouped into logical partitions, which are distributed across physical partitions, based on the partition key. The throughput on a container is evenly distributed across the physical partitions. To learn more about partitioning and partition keys, see Partition data.

When you create a container, you configure throughput in one of the following modes:

- **Dedicated provisioned throughput mode**: The throughput provisioned on a container is exclusively reserved for that container and it is backed by the SLAs. To learn more, see How to provision throughput on a container.
- **Shared provisioned throughput mode**: These containers share the provisioned throughput with the other containers in the same database (excluding containers that have been configured with dedicated provisioned throughput). In other words, the provisioned throughput on the database is shared among all the "shared throughput" containers. To learn more, see How to provision throughput on a database.

> **NOTE**
> You can configure shared and dedicated throughput only when creating the database and container. To switch from dedicated throughput mode to shared throughput mode (and vice versa) after the container is created, you have to create a new container and migrate the data to the new container. You can migrate the data by using the Azure Cosmos DB change feed feature.

An Azure Cosmos container can scale elastically, whether you create containers by using dedicated or shared provisioned throughput modes.

A container is a schema-agnostic container of items. Items in a container can have arbitrary schemas. For example, an item that represents a person and an item that represents an automobile can be placed in the *same container*. By default, all items that you add to a container are automatically indexed without requiring explicit index or schema management. You can customize the indexing behavior by configuring the indexing policy on a container.

You can set Time to Live (TTL) on selected items in a container or for the entire container to gracefully purge those items from the system. Azure Cosmos DB automatically deletes the items when they expire. It also guarantees that a query performed on the container doesn't return the expired items within a fixed bound. To learn more, see Configure TTL on your container.

You can use change feed to subscribe to the operations log that is managed for each logical partition of your container. Change feed provides the log of all the updates performed on the container, along with the before and after images of the items. For more information, see Build reactive applications by using change feed. You can also configure the retention duration for the change feed by using the change feed policy on the container.

You can register stored procedures, triggers, user-defined functions (UDFs), and merge procedures for your container.

You can specify a unique key constraint on your Azure Cosmos container. By creating a unique key policy, you ensure the uniqueness of one or more values per logical partition key. If you create a container by using a unique key policy, no new or updated items with values that duplicate the values specified by the unique key constraint can be created. To learn more, see Unique key constraints.

A container is specialized into API-specific entities as shown in the following table:

AZURE COSMOS ENTITY	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Azure Cosmos container	Container	Table	Collection	Graph	Table

> **NOTE**
> When creating containers, make sure you don't create two containers with the same name but different casing. That's because some parts of the Azure platform are not case-sensitive, and this can result in confusion/collision of telemetry and actions on containers with such names.

Properties of an Azure Cosmos container

An Azure Cosmos container has a set of system-defined properties. Depending on which API you use, some properties might not be directly exposed. The following table describes the list of system-defined properties:

SYSTEM-DEFINED PROPERTY	SYSTEM-GENERATED OR USER-CONFIGURABLE	PURPOSE	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
_rid	System-generated	Unique identifier of container	Yes	No	No	No	No
_etag	System-generated	Entity tag used for optimistic concurrency control	Yes	No	No	No	No
_ts	System-generated	Last updated timestamp of the container	Yes	No	No	No	No
_self	System-generated	Addressable URI of the container	Yes	No	No	No	No
id	User-configurable	User-defined unique name of the container	Yes	Yes	Yes	Yes	Yes

SYSTEM-DEFINED PROPERTY	SYSTEM-GENERATED OR USER-CONFIGURABLE	PURPOSE	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
indexingPolicy	User-configurable	Provides the ability to change the index path, index type, and index mode	Yes	No	No	No	Yes
TimeToLive	User-configurable	Provides the ability to delete items automatically from a container after a set time period. For details, see Time to Live.	Yes	No	No	No	Yes
changeFeedPolicy	User-configurable	Used to read changes made to items in a container. For details, see Change feed.	Yes	No	No	No	Yes
uniqueKeyPolicy	User-configurable	Used to ensure the uniqueness of one or more values in a logical partition. For more information, see Unique key constraints.	Yes	No	No	No	Yes

Operations on an Azure Cosmos container

An Azure Cosmos container supports the following operations when you use any of the Azure Cosmos APIs:

OPERATION	AZURE CLI	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Enumerate containers in a database	Yes	Yes	Yes	Yes	NA	NA
Read a container	Yes	Yes	Yes	Yes	NA	NA
Create a new container	Yes	Yes	Yes	Yes	NA	NA
Update a container	Yes	Yes	Yes	Yes	NA	NA
Delete a container	Yes	Yes	Yes	Yes	NA	NA

Azure Cosmos items

Depending on which API you use, an Azure Cosmos item can represent either a document in a collection, a row in a table, or a node or edge in a graph. The following table shows the mapping of API-specific entities to an Azure Cosmos item:

COSMOS ENTITY	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Azure Cosmos item	Item	Row	Document	Node or edge	Item

Properties of an item

Every Azure Cosmos item has the following system-defined properties. Depending on which API you use, some of them might not be directly exposed.

SYSTEM-DEFINED PROPERTY	SYSTEM-GENERATED OR USER-CONFIGURABLE	PURPOSE	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
_rid	System-generated	Unique identifier of the item	Yes	No	No	No	No
_etag	System-generated	Entity tag used for optimistic concurrency control	Yes	No	No	No	No

SYSTEM-DEFINED PROPERTY	SYSTEM-GENERATED OR USER-CONFIGURABLE	PURPOSE	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
_ts	System-generated	Timestamp of the last update of the item	Yes	No	No	No	No
_self	System-generated	Addressable URI of the item	Yes	No	No	No	No
id	Either	User-defined unique name in a logical partition.	Yes	Yes	Yes	Yes	Yes
Arbitrary user-defined properties	User-defined	User-defined properties represented in API-native representation (including JSON, BSON, and CQL)	Yes	Yes	Yes	Yes	Yes

NOTE

Uniqueness of the `id` property is only enforced within each logical partition. Multiple documents can have the same `id` property with different partition key values.

Operations on items

Azure Cosmos items support the following operations. You can use any of the Azure Cosmos APIs to perform the operations.

OPERATION	AZURE CLI	SQL API	CASSANDRA API	AZURE COSMOS DB API FOR MONGODB	GREMLIN API	TABLE API
Insert, Replace, Delete, Upsert, Read	No	Yes	Yes	Yes	Yes	Yes

Distribute your data globally with Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Today's applications are required to be highly responsive and always online. To achieve low latency and high availability, instances of these applications need to be deployed in datacenters that are close to their users. These applications are typically deployed in multiple datacenters and are called globally distributed. Globally distributed applications need a globally distributed database that can transparently replicate the data anywhere in the world to enable the applications to operate on a copy of the data that's close to its users.

Azure Cosmos DB is a globally distributed database system that allows you to read and write data from the local replicas of your database. Azure Cosmos DB transparently replicates the data to all the regions associated with your Cosmos account. Azure Cosmos DB is a globally distributed database service that's designed to provide low latency, elastic scalability of throughput, well-defined semantics for data consistency, and high availability. In short, if your application needs fast response time anywhere in the world, if it's required to be always online, and needs unlimited and elastic scalability of throughput and storage, you should build your application on Azure Cosmos DB.

You can configure your databases to be globally distributed and available in any of the Azure regions. To lower the latency, place the data close to where your users are. Choosing the required regions depends on the global reach of your application and where your users are located. Cosmos DB transparently replicates the data to all the regions associated with your Cosmos account. It provides a single system image of your globally distributed Azure Cosmos database and containers that your application can read and write to locally.

With Azure Cosmos DB, you can add or remove the regions associated with your account at any time. Your application doesn't need to be paused or redeployed to add or remove a region. It continues to be highly available all the time because of the multi-homing capabilities that the service natively provides.

Key benefits of global distribution

Build global active-active apps. With its novel multi-region writes replication protocol, every region supports both writes and reads. The multi-region writes capability also enables:

- Unlimited elastic write and read scalability.
- 99.999% read and write availability all around the world.
- Guaranteed reads and writes served in less than 10 milliseconds at the 99th percentile.

By using the Azure Cosmos DB multi-homing APIs, your application is aware of the nearest region and can send requests to that region. The nearest region is identified without any configuration changes. As you add and remove regions to and from your Azure Cosmos account, your application does not need to be redeployed or paused, it continues to be highly available at all times.

Build highly responsive apps. Your application can perform near real-time reads and writes against all the regions you chose for your database. Azure Cosmos DB internally handles the data replication between regions with consistency level guarantees of the level you've selected.

Build highly available apps. Running a database in multiple regions worldwide increases the availability of a database. If one region is unavailable, other regions automatically handle application requests. Azure Cosmos DB offers 99.999% read and write availability for multi-region databases.

Maintain business continuity during regional outages. Azure Cosmos DB supports automatic failover

during a regional outage. During a regional outage, Azure Cosmos DB continues to maintain its latency, availability, consistency, and throughput SLAs. To help make sure that your entire application is highly available, Cosmos DB offers a manual failover API to simulate a regional outage. By using this API, you can carry out regular business continuity drills.

Scale read and write throughput globally. You can enable every region to be writable and elastically scale reads and writes all around the world. The throughput that your application configures on an Azure Cosmos database or a container is provisioned across all regions associated with your Azure Cosmos account. The provisioned throughput is guaranteed up by financially backed SLAs.

Choose from several well-defined consistency models. The Azure Cosmos DB replication protocol offers five well-defined, practical, and intuitive consistency models. Each model has a tradeoff between consistency and performance. Use these consistency models to build globally distributed applications with ease.

Consistency levels in Azure Cosmos DB

11/2/2020 • 12 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Distributed databases that rely on replication for high availability, low latency, or both, must make a fundamental tradeoff between the read consistency, availability, latency, and throughput as defined by the PACLC theorem. The linearizability of the strong consistency model is the gold standard of data programmability. But it adds a steep price from higher write latencies due to data having to replicate and commit across large distances. Strong consistency may also suffer from reduced availability (during failures) because data cannot replicate and commit in every region. Eventual consistency offers higher availability and better performance, but its more difficult to program applications because data may not be completely consistent across all regions.

Most commercially available distributed NoSQL databases available in the market today provide only strong and eventual consistency. Azure Cosmos DB offers five well-defined levels. From strongest to weakest, the levels are:

- *Strong*
- *Bounded staleness*
- *Session*
- *Consistent prefix*
- *Eventual*

Each level provides availability and performance tradeoffs. The following image shows the different consistency levels as a spectrum.

The consistency levels are region-agnostic and are guaranteed for all operations regardless of the region from which the reads and writes are served, the number of regions associated with your Azure Cosmos account, or whether your account is configured with a single or multiple write regions.

Consistency levels and Azure Cosmos DB APIs

Azure Cosmos DB provides native support for wire protocol-compatible APIs for popular databases. These include MongoDB, Apache Cassandra, Gremlin, and Azure Table storage. When using Gremlin API and Table API, the default consistency level configured on the Azure Cosmos account is used. For details on consistency level mapping between Cassandra API or the API for MongoDB and Azure Cosmos DB's consistency levels see, Cassandra API consistency mapping and API for MongoDB consistency mapping.

Scope of the read consistency

Read consistency applies to a single read operation scoped within a logical partition. The read operation can be issued by a remote client or a stored procedure.

Configure the default consistency level

You can configure the default consistency level on your Azure Cosmos account at any time. The default consistency level configured on your account applies to all Azure Cosmos databases and containers under that account. All reads and queries issued against a container or a database use the specified consistency level by default. To learn more, see how to configure the default consistency level. You can also override the default consistency level for a specific request, to learn more, see how to Override the default consistency level article.

Guarantees associated with consistency levels

Azure Cosmos DB guarantees that 100 percent of read requests meet the consistency guarantee for the consistency level chosen. The precise definitions of the five consistency levels in Azure Cosmos DB using the TLA+ specification language are provided in the azure-cosmos-tla GitHub repo.

The semantics of the five consistency levels are described here:

- **Strong**: Strong consistency offers a linearizability guarantee. Linearizability refers to serving requests concurrently. The reads are guaranteed to return the most recent committed version of an item. A client never sees an uncommitted or partial write. Users are always guaranteed to read the latest committed write.

  The following graphic illustrates the strong consistency with musical notes. After the data is written to the "West US 2" region, when you read the data from other regions, you get the most recent value:

- **Bounded staleness**: The reads are guaranteed to honor the consistent-prefix guarantee. The reads might lag behind writes by at most *"K"* versions (that is, "updates") of an item or by *"T"* time interval, whichever is reached first. In other words, when you choose bounded staleness, the "staleness" can be configured in two ways:

- The number of versions (*K*) of the item

- The time interval (*T*) reads might lag behind the writes

For a single region account, the minimum value of *K* and *T* is 10 write operations or 5 seconds. For multi-region accounts the minimum value of *K* and *T* is 100,000 write operations or 300 seconds.

Bounded staleness offers total global order outside of the "staleness window." When a client performs read operations within a region that accepts writes, the guarantees provided by bounded staleness

consistency are identical to those guarantees by the strong consistency. As the staleness window approaches for either time or updates, whichever is closer, the service will throttle new writes to allow replication to catch up and honor the consistency guarantee.

Inside the staleness window, Bounded Staleness provides the following consistency guarantees:

- Consistency for clients in the same region for an account with single write region = Strong
- Consistency for clients in different regions for an account with single write region = Consistent Prefix
- Consistency for clients writing to a single region for an account with multiple write regions = Consistent Prefix
- Consistency for clients writing to different regions for an account with multiple write regions = Eventual

  Bounded staleness is frequently chosen by globally distributed applications that expect low write latencies but require total global order guarantee. Bounded staleness is great for applications featuring group collaboration and sharing, stock ticker, publish-subscribe/queueing etc. The following graphic illustrates the bounded staleness consistency with musical notes. After the data is written to the "West US 2" region, the "East US 2" and "Australia East" regions read the written value based on the configured maximum lag time or the maximum operations:

- **Session**: Within a single client session reads are guaranteed to honor the consistent-prefix, monotonic reads, monotonic writes, read-your-writes, and write-follows-reads guarantees. This assumes a single "writer" session or sharing the session token for multiple writers.

Clients outside of the session performing writes will see the following guarantees:

- Consistency for clients in same region for an account with single write region = Consistent Prefix
- Consistency for clients in different regions for an account with single write region = Consistent Prefix
- Consistency for clients writing to a single region for an account with multiple write regions = Consistent Prefix
- Consistency for clients writing to multiple regions for a account with multiple write regions = Eventual

Session consistency is the most widely used consistency level for both single region as well as globally distributed applications. It provides write latencies, availability, and read throughput comparable to that of eventual consistency but also provides the consistency guarantees that suit the needs of applications written to operate in the context of a user. The following graphic illustrates the session consistency with musical notes. The "West US 2 writer" and the "West US 2 reader" are using the same session (Session A) so they both read the same data at the same time. Whereas the "Australia East" region is using "Session B" so, it receives data later but in the same order as the writes.

- **Consistent prefix**: Updates that are returned contain some prefix of all the updates, with no gaps. Consistent prefix consistency level guarantees that reads never see out-of-order writes.

If writes were performed in the order `A, B, C`, then a client sees either `A`, `A,B`, or `A,B,C`, but never out-of-order permutations like `A,C` or `B,A,C`. Consistent Prefix provides write latencies, availability, and read throughput comparable to that of eventual consistency, but also provides the order guarantees that suit the needs of scenarios where order is important.

Below are the consistency guarantees for Consistent Prefix:

- Consistency for clients in same region for an account with single write region = Consistent Prefix
- Consistency for clients in different regions for an account with single write region = Consistent Prefix
- Consistency for clients writing to a single region for an account with multiple write region = Consistent Prefix
- Consistency for clients writing to multiple regions for an account with multiple write region = Eventual

The following graphic illustrates the consistency prefix consistency with musical notes. In all the regions, the reads never see out of order writes:

- **Eventual**: There's no ordering guarantee for reads. In the absence of any further writes, the replicas eventually converge.
  Eventual consistency is the weakest form of consistency because a client may read the values that are older than the ones it had read before. Eventual consistency is ideal where the application does not require any ordering guarantees. Examples include count of Retweets, Likes, or non-threaded comments. The following graphic illustrates the eventual consistency with musical notes.

Consistency guarantees in practice

In practice, you may often get stronger consistency guarantees. Consistency guarantees for a read operation correspond to the freshness and ordering of the database state that you request. Read-consistency is tied to the ordering and propagation of the write/update operations.

If there are no write operations on the database, a read operation with **eventual**, **session**, or **consistent prefix** consistency levels is likely to yield the same results as a read operation with strong consistency level.

If your Azure Cosmos account is configured with a consistency level other than the strong consistency, you can find out the probability that your clients may get strong and consistent reads for your workloads by looking at the *Probabilistically Bounded Staleness* (PBS) metric. This metric is exposed in the Azure portal, to learn more, see Monitor Probabilistically Bounded Staleness (PBS) metric.

Probabilistic bounded staleness shows how eventual is your eventual consistency. This metric provides an insight into how often you can get a stronger consistency than the consistency level that you have currently configured on your Azure Cosmos account. In other words, you can see the probability (measured in milliseconds) of getting strongly consistent reads for a combination of write and read regions.

Consistency levels and latency

The read latency for all consistency levels is always guaranteed to be less than 10 milliseconds at the 99th percentile. The average read latency, at the 50th percentile, is typically 4 milliseconds or less.

The write latency for all consistency levels is always guaranteed to be less than 10 milliseconds at the 99th percentile. The average write latency, at the 50th percentile, is usually 5 milliseconds or less. Azure Cosmos accounts that span several regions and are configured with strong consistency are an exception to this guarantee.

Write latency and Strong consistency

For Azure Cosmos accounts configured with strong consistency with more than one region, the write latency is equal to two times round-trip time (RTT) between any of the two farthest regions, plus 10 milliseconds at the 99th percentile. High network RTT between the regions will translate to higher latency for Cosmos DB requests since strong consistency completes an operation only after ensuring that it has been committed to all regions within an account.

The exact RTT latency is a function of speed-of-light distance and the Azure networking topology. Azure networking doesn't provide any latency SLAs for the RTT between any two Azure regions, however it does publish Azure network round-trip latency statistics. For your Azure Cosmos account, replication latencies are displayed in the Azure portal. You can use the Azure portal (go to the Metrics blade, select Consistency tab) to monitor the replication latencies between various regions that are associated with your Azure Cosmos account.

> **IMPORTANT**
> Strong consistency for accounts with regions spanning more than 5000 miles (8000 kilometers) is blocked by default due to high write latency. To enable this capability please contact support.

Consistency levels and throughput

- For strong and bounded staleness, reads are done against two replicas in a four replica set (minority quorum) to provide consistency guarantees. Session, consistent prefix and eventual do single replica reads. The result is that, for the same number of request units, read throughput for strong and bounded staleness is half of the other consistency levels.
- For a given type of write operation, such as insert, replace, upsert, and delete, the write throughput for request units is identical for all consistency levels.

CONSISTENCY LEVEL	QUORUM READS	QUORUM WRITES
Strong	Local Minority	Global Majority
Bounded Staleness	Local Minority	Local Majority
Session	Single Replica (using session token)	Local Majority

CONSISTENCY LEVEL	QUORUM READS	QUORUM WRITES
Consistent Prefix	Single Replica	Local Majority
Eventual	Single Replica	Local Majority

> **NOTE**
> The RU/s cost of reads for Local Minority reads are twice that of weaker consistency levels because reads are made from two replicas to provide consistency guarantees for Strong and Bounded Staleness.

Consistency levels and data durability

Within a globally distributed database environment there is a direct relationship between the consistency level and data durability in the presence of a region-wide outage. As you develop your business continuity plan, you need to understand the maximum acceptable time before the application fully recovers after a disruptive event. The time required for an application to fully recover is known as **recovery time objective** (RTO). You also need to understand the maximum period of recent data updates the application can tolerate losing when recovering after a disruptive event. The time period of updates that you might afford to lose is known as **recovery point objective** (RPO).

The table below defines the relationship between consistency model and data durability in the presence of a region wide outage. It is important to note that in a distributed system, even with strong consistency, it is impossible to have a distributed database with an RPO and RTO of zero due to CAP Theorem.

REGION(S)	REPLICATION MODE	CONSISTENCY LEVEL	RPO	RTO
1	Single or Multiple write regions	Any Consistency Level	< 240 Minutes	<1 Week
>1	Single write region	Session, Consistent Prefix, Eventual	< 15 minutes	< 15 minutes
>1	Single write region	Bounded Staleness	*K* & *T*	< 15 minutes
>1	Single write region	Strong	0	< 15 minutes
>1	Multiple write regions	Session, Consistent Prefix, Eventual	< 15 minutes	0
>1	Multiple write regions	Bounded Staleness	*K* & *T*	0

K = The number of *"K"* versions (i.e., updates) of an item.

T = The time interval *"T"* since the last update.

For a single region account, the minimum value of *K* and *T* is 10 write operations or 5 seconds. For multi-region accounts the minimum value of *K* and *T* is 100,000 write operations or 300 seconds. This defines the minimum RPO for data when using Bounded Staleness.

Strong consistency and multiple write regions

Cosmos accounts configured with multiple write regions cannot be configured for strong consistency as it is not possible for a distributed system to provide an RPO of zero and an RTO of zero. Additionally, there are no write latency benefits on using strong consistency with multiple write regions because a write to any region must be replicated and committed to all configured regions within the account. This results in the same write latency as a single write region account.

How does Azure Cosmos DB provide high availability

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB provides high availability in two primary ways. First, Azure Cosmos DB replicates data across regions configured within a Cosmos account. Second, Azure Cosmos DB maintains 4 replicas of data within a region.

Azure Cosmos DB is a globally distributed database service and is a foundational service in Azure. By default, is available in all regions where Azure is available. You can associate any number of Azure regions with your Azure Cosmos account and your data is automatically and transparently replicated. You can add or remove a region to your Azure Cosmos account at any time. Cosmos DB is available in all five distinct Azure cloud environments available to customers:

- **Azure public** cloud, which is available globally.
- **Azure China 21Vianet** is available through a unique partnership between Microsoft and 21Vianet, one of the country's largest internet providers in China.
- **Azure Germany** provides services under a data trustee model, which ensures that customer data remains in Germany under the control of T-Systems International GmbH, a subsidiary of Deutsche Telekom, acting as the German data trustee.
- **Azure Government** is available in four regions in the United States to US government agencies and their partners.
- **Azure Government for Department of Defense (DoD)** is available in two regions in the United States to the US Department of Defense.

Within a region, Azure Cosmos DB maintains four copies of your data as replicas within physical partitions as shown in the following image:

- The data within Azure Cosmos containers is horizontally partitioned.
- A partition-set is a collection of multiple replica-sets. Within each region, every partition is protected by a replica-set with all writes replicated and durably committed by a majority of replicas. Replicas are distributed across as many as 10-20 fault domains.
- Each partition across all the regions is replicated. Each region contains all the data partitions of an Azure Cosmos container and can accept writes and serve reads.

If your Azure Cosmos account is distributed across *N* Azure regions, there will be at least *N* x 4 copies of all your data. Having an Azure Cosmos account in more than 2 regions improves the availability of your application and provides low latency across the associated regions.

SLAs for availability

As a globally distributed database, Azure Cosmos DB provides comprehensive SLAs that encompass throughput, latency at the 99th percentile, consistency, and high availability. The table below shows the guarantees for high availability provided by Azure Cosmos DB for single and multi-region accounts. For high availability, always configure your Azure Cosmos accounts to have multiple write regions.

OPERATION TYPE	SINGLE REGION	MULTI-REGION (SINGLE REGION WRITES)	MULTI-REGION (MULTI-REGION WRITES)
Writes	99.99	99.99	99.999
Reads	99.99	99.999	99.999

> **NOTE**
>
> In practice, the actual write availability for bounded staleness, session, consistent prefix and eventual consistency models is significantly higher than the published SLAs. The actual read availability for all consistency levels is significantly higher than the published SLAs.

High availability with Azure Cosmos DB in the event of regional outages

For the rare cases of regional outage, Azure Cosmos DB makes sure your database is always highly available. The following details capture Azure Cosmos DB behavior during an outage, depending on your Azure Cosmos account configuration:

- With Azure Cosmos DB, before a write operation is acknowledged to the client, the data is durably committed by a quorum of replicas within the region that accepts the write operations. For more details, see Consistency levels and throughput
- Multi-region accounts configured with multiple-write regions will be highly available for both writes and reads. Regional failovers are detected and handled in the Azure Cosmos DB client. They are also instantaneous and don't require any changes from the application.
- Single-region accounts may lose availability following a regional outage. It's always recommended to set up **at least two regions** (preferably, at least two write regions) with your Azure Cosmos account to ensure high availability at all times.

Multi-region accounts with a single-write region (write region outage)

- During a write region outage, the Azure Cosmos account will automatically promote a secondary region to be the new primary write region when **enable automatic failover** is configured on the Azure Cosmos account. When enabled, the failover will occur to another region in the order of region priority you've specified.
- When the previously impacted region is back online, any write data that was not replicated when the region failed, is made available through the conflicts feed. Applications can read the conflicts feed, resolve the conflicts based on the application-specific logic, and write the updated data back to the Azure Cosmos container as appropriate.
- Once the previously impacted write region recovers, it becomes automatically available as a read region. You can switch back to the recovered region as the write region. You can switch the regions by using PowerShell, Azure CLI or Azure portal. There is **no data or availability loss** before, during or after you switch the write region and your application continues to be highly available.

> **IMPORTANT**
>
> It is strongly recommended that you configure the Azure Cosmos accounts used for production workloads to **enable automatic failover**. Manual failover requires connectivity between secondary and primary write region to complete a consistency check to ensure there is no data loss during the failover. If the primary region is unavailable, this consistency check cannot complete and the manual failover will not succeed, resulting in loss of write availability for the duration of the regional outage.

Multi-region accounts with a single-write region (read region outage)

- During a read region outage, Azure Cosmos accounts using any consistency level or strong consistency with three or more read regions will remain highly available for reads and writes.
- Azure Cosmos accounts using strong consistency with two or fewer read regions (which includes the read & write region) will lose read write availability during a read region outage.
- The impacted region is automatically disconnected and will be marked offline. The Azure Cosmos DB SDKs will redirect read calls to the next available region in the preferred region list.
- If none of the regions in the preferred region list is available, calls automatically fall back to the current write region.

- No changes are required in your application code to handle read region outage. When the impacted read region is back online it will automatically sync with the current write region and will be available again to serve read requests.
- Subsequent reads are redirected to the recovered region without requiring any changes to your application code. During both failover and rejoining of a previously failed region, read consistency guarantees continue to be honored by Azure Cosmos DB.
- Even in a rare and unfortunate event when the Azure region is permanently irrecoverable, there is no data loss if your multi-region Azure Cosmos account is configured with *Strong* consistency. In the event of a permanently irrecoverable write region, a multi-region Azure Cosmos account configured with bounded-staleness consistency, the potential data loss window is restricted to the staleness window (*K* or *T*) where K=100,000 updates and T=5 minutes. For session, consistent-prefix and eventual consistency levels, the potential data loss window is restricted to a maximum of 15 minutes. For more information on RTO and RPO targets for Azure Cosmos DB, see Consistency levels and data durability

Availability Zone support

In addition to cross region resiliency, you can now enable **zone redundancy** when selecting a region to associate with your Azure Cosmos database.

With Availability Zone support, Azure Cosmos DB will ensure replicas are placed across multiple zones within a given region to provide high availability and resiliency during zonal failures. There are no changes to latency and other SLAs in this configuration. In the event of a single zone failure, zone redundancy provides full data durability with RPO=0 and availability with RTO=0.

Zone redundancy is a *supplemental capability* to the replication in multi-region writes feature. Zone redundancy alone cannot be relied upon to achieve regional resiliency. For example, in the event of regional outages or low latency access across the regions, it's advised to have multiple write regions in addition to zone redundancy.

When configuring multi-region writes for your Azure Cosmos account, you can opt into zone redundancy at no extra cost. Otherwise, please see the note below regarding the pricing for zone redundancy support. You can enable zone redundancy on an existing region of your Azure Cosmos account by removing the region and adding it back with the zone redundancy enabled. For a list of regions where availability zones are supported, see the Availability zones documentation.

The following table summarizes the high availability capability of various account configurations:

KPI	SINGLE REGION WITHOUT AVAILABILITY ZONES (NON-AZ)	SINGLE REGION WITH AVAILABILITY ZONES (AZ)	MULTI-REGION WRITES WITH AVAILABILITY ZONES (AZ, 2 REGIONS) – MOST RECOMMENDED SETTING
Write availability SLA	99.99%	99.99%	99.999%
Read availability SLA	99.99%	99.99%	99.999%
Price	Single region billing rate	Single region Availability Zone billing rate	Multi-region billing rate
Zone failures – data loss	Data loss	No data loss	No data loss
Zone failures – availability	Availability loss	No availability loss	No availability loss
Read latency	Cross region	Cross region	Low

KPI	SINGLE REGION WITHOUT AVAILABILITY ZONES (NON-AZ)	SINGLE REGION WITH AVAILABILITY ZONES (AZ)	MULTI-REGION WRITES WITH AVAILABILITY ZONES (AZ, 2 REGIONS) – MOST RECOMMENDED SETTING
Write latency	Cross region	Cross region	Low
Regional outage – data loss	Data loss	Data loss	Data loss When using bounded staleness consistency with multiple write regions and more than one region, data loss is limited to the bounded staleness configured on your account You can avoid data loss during a regional outage by configuring strong consistency with multiple regions. This option comes with trade-offs that affect availability and performance. It can be configured only on accounts that are configured for single-region writes.
Regional outage – availability	Availability loss	Availability loss	No availability loss
Throughput	X RU/s provisioned throughput	X RU/s provisioned throughput * 1.25	2X RU/s provisioned throughput This configuration mode requires twice the amount of throughput when compared to a single region with Availability Zones because there are two regions.

NOTE

To enable Availability Zone support for a multi region Azure Cosmos account, the account must have multi-region writes enabled.

You can enable zone redundancy when adding a region to new or existing Azure Cosmos accounts. To enable zone redundancy on your Azure Cosmos account, you should set the `isZoneRedundant` flag to `true` for a specific location. You can set this flag within the locations property. For example, the following PowerShell snippet enables zone redundancy for the "Southeast Asia" region:

Availability Zones can be enabled via:

- Azure portal
- Azure PowerShell
- Azure CLI

- Azure Resource Manager templates

Building highly available applications

- Review the expected behavior of the Azure Cosmos SDKs during these events and which are the configurations that affect it.
- To ensure high write and read availability, configure your Azure Cosmos account to span at least two regions with multiple-write regions. This configuration will provide the highest availability, lowest latency, and best scalability for both reads and writes backed by SLAs. To learn more, see how to configure your Azure Cosmos account with multiple write-regions.
- For multi-region Azure Cosmos accounts that are configured with a single-write region, enable automatic-failover by using Azure CLI or Azure portal. After you enable automatic failover, whenever there is a regional disaster, Cosmos DB will automatically failover your account.
- Even if your Azure Cosmos account is highly available, your application may not be correctly designed to remain highly available. To test the end-to-end high availability of your application, as a part of your application testing or disaster recovery (DR) drills, temporarily disable automatic-failover for the account, invoke the manual failover by using PowerShell, Azure CLI or Azure portal, then monitor your application's failover. Once complete, you can fail back over to the primary region and restore automatic-failover for the account.
- Within a globally distributed database environment, there is a direct relationship between the consistency level and data durability in the presence of a region-wide outage. As you develop your business continuity plan, you need to understand the maximum acceptable time before the application fully recovers after a disruptive event. The time required for an application to fully recover is known as recovery time objective (RTO). You also need to understand the maximum period of recent data updates the application can tolerate losing when recovering after a disruptive event. The time period of updates that you might afford to lose is known as recovery point objective (RPO). To see the RPO and RTO for Azure Cosmos DB, see Consistency levels and data durability

Conflict types and resolution policies when using multiple write regions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Conflicts and conflict resolution policies are applicable if your Azure Cosmos DB account is configured with multiple write regions.

For Azure Cosmos accounts configured with multiple write regions, update conflicts can occur when writers concurrently update the same item in multiple regions. Update conflicts can be of the following three types:

- **Insert conflicts**: These conflicts can occur when an application simultaneously inserts two or more items with the same unique index in two or more regions. For example, this conflict might occur with an ID property.
- **Replace conflicts**: These conflicts can occur when an application updates the same item simultaneously in two or more regions.
- **Delete conflicts**: These conflicts can occur when an application simultaneously deletes an item in one region and updates it in another region.

Conflict resolution policies

Azure Cosmos DB offers a flexible policy-driven mechanism to resolve write conflicts. You can select from two conflict resolution policies on an Azure Cosmos container:

- **Last Write Wins (LWW)**: This resolution policy, by default, uses a system-defined timestamp property. It's based on the time-synchronization clock protocol. If you use the SQL API, you can specify any other custom numerical property (e.g., your own notion of a timestamp) to be used for conflict resolution. A custom numerical property is also referred to as the *conflict resolution path*.

  If two or more items conflict on insert or replace operations, the item with the highest value for the conflict resolution path becomes the winner. The system determines the winner if multiple items have the same numeric value for the conflict resolution path. All regions will converge to a single winner and end up with the same version of the committed item. When delete conflicts are involved, the deleted version always wins over either insert or replace conflicts. This outcome occurs no matter what the value of the conflict resolution path is.

  > **NOTE**
  > Last Write Wins is the default conflict resolution policy and uses timestamp `_ts` for the following APIs: SQL, MongoDB, Cassandra, Gremlin and Table. Custom numerical property is available only for SQL API.

  To learn more, see examples that use LWW conflict resolution policies.

- **Custom**: This resolution policy is designed for application-defined semantics for reconciliation of conflicts. When you set this policy on your Azure Cosmos container, you also need to register a *merge stored procedure*. This procedure is automatically invoked when conflicts are detected under a database transaction on the server. The system provides exactly once guarantee for the execution of a merge procedure as part of

the commitment protocol.

If you configure your container with the custom resolution option, and you fail to register a merge procedure on the container or the merge procedure throws an exception at runtime, the conflicts are written to the *conflicts feed*. Your application then needs to manually resolve the conflicts in the conflicts feed. To learn more, see examples of how to use the custom resolution policy and how to use the conflicts feed.

> **NOTE**
>
> Custom conflict resolution policy is available only for SQL API accounts.

Global data distribution with Azure Cosmos DB - under the hood

11/2/2020 • 9 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB is a foundational service in Azure, so it's deployed across all Azure regions worldwide including the public, sovereign, Department of Defense (DoD) and government clouds. Within a data center, we deploy and manage the Azure Cosmos DB on massive stamps of machines, each with dedicated local storage. Within a data center, Azure Cosmos DB is deployed across many clusters, each potentially running multiple generations of hardware. Machines within a cluster are typically spread across 10-20 fault domains for high availability within a region. The following image shows the Cosmos DB global distribution system topology:

Global distribution in Azure Cosmos DB is turnkey: At any time, with a few clicks or programmatically with a single API call, you can add or remove the geographical regions associated with your Cosmos database. A Cosmos database, in turn, consists of a set of Cosmos containers. In Cosmos DB, containers serve as the logical units of distribution and scalability. The collections, tables, and graphs you create are (internally) just Cosmos containers. Containers are completely schema-agnostic and provide a scope for a query. Data in a Cosmos container is automatically indexed upon ingestion. Automatic indexing enables users to query the data without the hassles of schema or index management, especially in a globally distributed setup.

- In a given region, data within a container is distributed by using a partition-key, which you provide and is transparently managed by the underlying physical partitions (*local distribution*).
- Each physical partition is also replicated across geographical regions (*global distribution*).

When an app using Cosmos DB elastically scales throughput on a Cosmos container or consumes more storage, Cosmos DB transparently handles partition management operations (split, clone, delete) across all the regions. Independent of the scale, distribution, or failures, Cosmos DB continues to provide a single system image of the

data within the containers, which are globally distributed across any number of regions.

As shown in the following image, the data within a container is distributed along two dimensions - within a region and across regions, worldwide:

A physical partition is implemented by a group of replicas, called a *replica-set*. Each machine hosts hundreds of replicas that correspond to various physical partitions within a fixed set of processes as shown in the image above. Replicas corresponding to the physical partitions are dynamically placed and load balanced across the machines within a cluster and data centers within a region.

A replica uniquely belongs to an Azure Cosmos DB tenant. Each replica hosts an instance of Cosmos DB's database engine, which manages the resources as well as the associated indexes. The Cosmos database engine operates on an atom-record-sequence (ARS) based type system. The engine is agnostic to the concept of a schema, blurring the boundary between the structure and instance values of records. Cosmos DB achieves full schema agnosticism by automatically indexing everything upon ingestion in an efficient manner, which allows users to query their globally distributed data without having to deal with schema or index management.

The Cosmos database engine consists of components including implementation of several coordination primitives, language runtimes, the query processor, and the storage and indexing subsystems responsible for transactional storage and indexing of data, respectively. To provide durability and high availability, the database engine persists its data and index on SSDs and replicates it among the database engine instances within the replica-set(s) respectively. Larger tenants correspond to higher scale of throughput and storage and have either bigger or more replicas or both. Every component of the system is fully asynchronous – no thread ever blocks, and each thread does short-lived work without incurring any unnecessary thread switches. Rate-limiting and back-pressure are plumbed across the entire stack from the admission control to all I/O paths. Cosmos database engine is designed to exploit fine-grained concurrency and to deliver high throughput while operating within frugal amounts of system resources.

Cosmos DB's global distribution relies on two key abstractions – *replica-sets* and *partition-sets*. A replica-set is a modular Lego block for coordination, and a partition-set is a dynamic overlay of one or more geographically distributed physical partitions. To understand how global distribution works, we need to understand these two key abstractions.

Replica-sets

A physical partition is materialized as a self-managed and dynamically load-balanced group of replicas spread across multiple fault domains, called a replica-set. This set collectively implements the replicated state machine protocol to make the data within the physical partition highly available, durable, and consistent. The replica-set membership *N* is dynamic – it keeps fluctuating between *NMin* and *NMax* based on the failures, administrative operations, and the time for failed replicas to regenerate/recover. Based on the membership changes, the replication protocol also reconfigures the size of read and write quorums. To uniformly distribute the throughput that is assigned to a given physical partition, we employ two ideas:

- First, the cost of processing the write requests on the leader is higher than the cost of applying the updates on the follower. Correspondingly, the leader is budgeted more system resources than the followers.
- Secondly, as far as possible, the read quorum for a given consistency level is composed exclusively of the follower replicas. We avoid contacting the leader for serving reads unless required. We employ a number of ideas from the research done on the relationship of load and capacity in the quorum-based systems for the five consistency models that Cosmos DB supports.

Partition-sets

A group of physical partitions, one from each of the configured with the Cosmos database regions, is composed to manage the same set of keys replicated across all the configured regions. This higher coordination primitive is called a *partition-set* - a geographically distributed dynamic overlay of physical partitions managing a given set of keys. While a given physical partition (a replica-set) is scoped within a cluster, a partition-set can span clusters, data centers, and geographical regions as shown in the image below:

You can think of a partition-set as a geographically dispersed "super replica-set", which is composed of multiple replica-sets owning the same set of keys. Similar to a replica-set, a partition-set's membership is also dynamic – it fluctuates based on implicit physical partition management operations to add/remove new partitions to/from a

given partition-set (for instance, when you scale out throughput on a container, add/remove a region to your Cosmos database, or when failures occur). By virtue of having each of the partitions (of a partition-set) manage the partition-set membership within its own replica-set, the membership is fully decentralized and highly available. During the reconfiguration of a partition-set, the topology of the overlay between physical partitions is also established. The topology is dynamically selected based on the consistency level, geographical distance, and available network bandwidth between the source and the target physical partitions.

The service allows you to configure your Cosmos databases with either a single write region or multiple write regions, and depending on the choice, partition-sets are configured to accept writes in exactly one or all regions. The system employs a two-level, nested consensus protocol – one level operates within the replicas of a replica-set of a physical partition accepting the writes, and the other operates at the level of a partition-set to provide complete ordering guarantees for all the committed writes within the partition-set. This multi-layered, nested consensus is critical for the implementation of our stringent SLAs for high availability, as well as the implementation of the consistency models, which Cosmos DB offers to its customers.

Conflict resolution

Our design for the update propagation, conflict resolution, and causality tracking is inspired from the prior work on epidemic algorithms and the Bayou system. While the kernels of the ideas have survived and provide a convenient frame of reference for communicating the Cosmos DB's system design, they have also undergone significant transformation as we applied them to the Cosmos DB system. This was needed, because the previous systems were designed neither with the resource governance nor with the scale at which Cosmos DB needs to operate, nor to provide the capabilities (for example, bounded staleness consistency) and the stringent and comprehensive SLAs that Cosmos DB delivers to its customers.

Recall that a partition-set is distributed across multiple regions and follows Cosmos DBs (multi-region writes) replication protocol to replicate the data among the physical partitions comprising a given partition-set. Each physical partition (of a partition-set) accepts writes and serves reads typically to the clients that are local to that region. Writes accepted by a physical partition within a region are durably committed and made highly available within the physical partition before they are acknowledged to the client. These are tentative writes and are propagated to other physical partitions within the partition-set using an anti-entropy channel. Clients can request either tentative or committed writes by passing a request header. The anti-entropy propagation (including the frequency of propagation) is dynamic, based on the topology of the partition-set, regional proximity of the physical partitions, and the consistency level configured. Within a partition-set, Cosmos DB follows a primary commit scheme with a dynamically selected arbiter partition. The arbiter selection is dynamic and is an integral part of the reconfiguration of the partition-set based on the topology of the overlay. The committed writes (including multi-row/batched updates) are guaranteed to be ordered.

We employ encoded vector clocks (containing region ID and logical clocks corresponding to each level of consensus at the replica-set and partition-set, respectively) for causality tracking and version vectors to detect and resolve update conflicts. The topology and the peer selection algorithm are designed to ensure fixed and minimal storage and minimal network overhead of version vectors. The algorithm guarantees the strict convergence property.

For the Cosmos databases configured with multiple write regions, the system offers a number of flexible automatic conflict resolution policies for the developers to choose from, including:

- **Last-Write-Wins (LWW)**, which, by default, uses a system-defined timestamp property (which is based on the time-synchronization clock protocol). Cosmos DB also allows you to specify any other custom numerical property to be used for conflict resolution.
- **Application-defined (Custom) conflict resolution policy** (expressed via merge procedures), which is designed for application-defined semantics reconciliation of conflicts. These procedures get invoked upon detection of the write-write conflicts under the auspices of a database transaction on the server side. The system provides exactly once guarantee for the execution of a merge procedure as a part of the commitment

protocol. There are several conflict resolution samples available for you to play with.

Consistency Models

Whether you configure your Cosmos database with a single or multiple write regions, you can choose from the five well-defined consistency models. With multiple write regions, the following are a few notable aspects of the consistency levels:

The bounded staleness consistency guarantees that all reads will be within *K* prefixes or *T* seconds from the latest write in any of the regions. Furthermore, reads with bounded staleness consistency are guaranteed to be monotonic and with consistent prefix guarantees. The anti-entropy protocol operates in a rate-limited manner and ensures that the prefixes do not accumulate and the backpressure on the writes does not have to be applied. Session consistency guarantees monotonic read, monotonic write, read your own writes, write follows read, and consistent prefix guarantees, worldwide. For the databases configured with strong consistency, the benefits (low write latency, high write availability) of multiple write regions does not apply, because of synchronous replication across regions.

The semantics of the five consistency models in Cosmos DB are described here, and mathematically described using a high-level TLA+ specifications here.

Partitioning and horizontal scaling in Azure Cosmos DB

11/2/2020 • 9 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB uses partitioning to scale individual containers in a database to meet the performance needs of your application. In partitioning, the items in a container are divided into distinct subsets called *logical partitions*. Logical partitions are formed based on the value of a *partition key* that is associated with each item in a container. All the items in a logical partition have the same partition key value.

For example, a container holds items. Each item has a unique value for the `UserID` property. If `UserID` serves as the partition key for the items in the container and there are 1,000 unique `UserID` values, 1,000 logical partitions are created for the container.

In addition to a partition key that determines the item's logical partition, each item in a container has an *item ID* (unique within a logical partition). Combining the partition key and the *item ID* creates the item's *index*, which uniquely identifies the item. Choosing a partition key is an important decision that will affect your application's performance.

This article explains the relationship between logical and physical partitions. It also discusses best practices for partitioning and gives an in-depth view at how horizontal scaling works in Azure Cosmos DB. It's not necessary to understand these internal details to select your partition key but we have covered them so you have clarity on how Azure Cosmos DB works.

Logical partitions

A logical partition consists of a set of items that have the same partition key. For example, in a container that contains data about food nutrition, all items contain a `foodGroup` property. You can use `foodGroup` as the partition key for the container. Groups of items that have specific values for `foodGroup`, such as `Beef Products`, `Baked Products`, and `Sausages and Luncheon Meats`, form distinct logical partitions. You don't have to worry about deleting a logical partition when the underlying data is deleted.

A logical partition also defines the scope of database transactions. You can update items within a logical partition by using a transaction with snapshot isolation. When new items are added to a container, new logical partitions are transparently created by the system.

There is no limit to the number of logical partitions in your container. Each logical partition can store up to 20GB of data. Good partition key choices have a wide range of possible values. For example, in a container where all items contain a `foodGroup` property, the data within the `Beef Products` logical partition can grow up to 20 GB. Selecting a partition key with a wide range of possible values ensures that the container is able to scale.

Physical partitions

A container is scaled by distributing data and throughput across physical partitions. Internally, one or more logical partitions are mapped to a single physical partition. Typically smaller containers have many logical partitions but they only require a single physical partition. Unlike logical partitions,

physical partitions are an internal implementation of the system and they are entirely managed by Azure Cosmos DB.

The number of physical partitions in your container depends on the following configuration:

- The number of throughput provisioned (each individual physical partition can provide a throughput of up to 10,000 request units per second).
- The total data storage (each individual physical partition can store up to 50GB data).

There is no limit to the total number of physical partitions in your container. As your provisioned throughput or data size grows, Azure Cosmos DB will automatically create new physical partitions by splitting existing ones. Physical partition splits do not impact your application's availability. After the physical partition split, all data within a single logical partition will still be stored on the same physical partition. A physical partition split simply creates a new mapping of logical partitions to physical partitions.

Throughput provisioned for a container is divided evenly among physical partitions. A partition key design that doesn't distribute requests evenly might result in too many requests directed to a small subset of partitions that become "hot." Hot partitions lead to inefficient use of provisioned throughput, which might result in rate-limiting and higher costs.

You can see your container's physical partitions in the **Storage** section of the **Metrics blade** of the Azure portal:

In the above screenshot, a container has `/foodGroup` as the partition key. Each of the three bars in the graph represents a physical partition. In the image, **partition key range** is the same as a physical partition. The selected physical partition contains three logical partitions: `Beef Products`, `Vegetable and Vegetable Products`, and `Soups, Sauces, and Gravies`.

If you provision a throughput of 18,000 request units per second (RU/s), then each of the three physical

partition can utilize 1/3 of the total provisioned throughput. Within the selected physical partition, the logical partition keys `Beef Products`, `Vegetable and Vegetable Products`, and `Soups, Sauces, and Gravies` can, collectively, utilize the physical partition's 6,000 provisioned RU/s. Because provisioned throughput is evenly divided across your container's physical partitions, it's important to choose a partition key that evenly distributes throughput consumption by choosing the right logical partition key.

> **NOTE**
>
> If you choose a partition key that evenly distributes throughput consumption across logical partitions, you will ensure that throughput consumption across physical partitions is balanced.

Managing logical partitions

Azure Cosmos DB transparently and automatically manages the placement of logical partitions on physical partitions to efficiently satisfy the scalability and performance needs of the container. As the throughput and storage requirements of an application increase, Azure Cosmos DB moves logical partitions to automatically spread the load across a greater number of physical partitions. You can learn more about physical partitions.

Azure Cosmos DB uses hash-based partitioning to spread logical partitions across physical partitions. Azure Cosmos DB hashes the partition key value of an item. The hashed result determines the physical partition. Then, Azure Cosmos DB allocates the key space of partition key hashes evenly across the physical partitions.

Transactions (in stored procedures or triggers) are allowed only against items in a single logical partition.

You can learn more about how Azure Cosmos DB manages partitions. (It's not necessary to understand the internal details to build or run your applications, but added here for a curious reader.)

Replica sets

Each physical partition consists of a set of replicas, also referred to as a *replica set*. Each replica set hosts an instance of the database engine. A replica set makes the data stored within the physical partition durable, highly available, and consistent. Each replica that makes up the physical partition inherits the partition's storage quota. All replicas of a physical partition collectively support the throughput that's allocated to the physical partition. Azure Cosmos DB automatically manages replica sets.

Typically smaller containers only require a single physical partition but they will still have at least 4 replicas.

The following image shows how logical partitions are mapped to physical partitions that are distributed globally:

Choosing a partition key

A partition key has two components: **partition key path** and the **partition key value**. For example, consider an item { "userId" : "Andrew", "worksFor": "Microsoft" } if you choose "userId" as the partition key, the following are the two partition key components:

- The partition key path (For example: "/userId"). The partition key path accepts alphanumeric and underscore(_) characters. You can also use nested objects by using the standard path notation(/).
- The partition key value (For example: "Andrew"). The partition key value can be of string or numeric types.

To learn about the limits on throughput, storage, and length of the partition key, see the Azure Cosmos DB service quotas article.

Selecting your partition key is a simple but important design choice in Azure Cosmos DB. Once you select your partition key, it is not possible to change it in-place. If you need to change your partition key, you should move your data to a new container with your new desired partition key.

For **all** containers, your partition key should:

- Be a property that has a value which does not change. If a property is your partition key, you can't update that property's value.
- Have a high cardinality. In other words, the property should have a wide range of possible values.
- Spread request unit (RU) consumption and data storage evenly across all logical partitions. This ensures even RU consumption and storage distribution across your physical partitions.

If you need multi-item ACID transactions in Azure Cosmos DB, you will need to use stored procedures or triggers. All JavaScript-based stored procedures and triggers are scoped to a single logical partition.

Partition keys for read-heavy containers

For most containers, the above criteria is all you need to consider when picking a partition key. For large read-heavy containers, however, you might want to choose a partition key that appears frequently as a filter in your queries. Queries can be efficiently routed to only the relevant physical partitions by including the partition key in the filter predicate.

If most of your workload's requests are queries and most of your queries have an equality filter on the same property, this property can be a good partition key choice. For example, if you frequently run a query that filters on `UserID`, then selecting `UserID` as the partition key would reduce the number of cross-partition queries.

However, if your container is small, you probably don't have enough physical partitions to need to worry about the performance impact of cross-partition queries. Most small containers in Azure Cosmos DB only require one or two physical partitions.

If your container could grow to more than a few physical partitions, then you should make sure you pick a partition key that minimizes cross-partition queries. Your container will require more than a few physical partitions when either of the following are true:

- Your container will have over 30,000 RU's provisioned
- Your container will store over 100 GB of data

Using item ID as the partition key

If your container has a property that has a wide range of possible values, it is likely a great partition key choice. One possible example of such a property is the *item ID*. For small read-heavy containers or write-heavy containers of any size, the *item ID* is naturally a great choice for the partition key.

The system property *item ID* exists in every item in your container. You may have other properties that represent a logical ID of your item. In many cases, these are also great partition key choices for the same reasons as the *item ID*.

The *item ID* is a great partition key choice for the following reasons:

- There are a wide range of possible values (one unique *item ID* per item).
- Because there is a unique *item ID* per item, the *item ID* does a great job at evenly balancing RU consumption and data storage.
- You can easily do efficient point reads since you'll always know an item's partition key if you know its *item ID*.

Some things to consider when selecting the *item ID* as the partition key include:

- If the *item ID* is the partition key, it will become a unique identifier throughout your entire container. You won't be able to have items that have a duplicate *item ID*.
- If you have a read-heavy container that has a lot of physical partitions, queries will be more efficient if they have an equality filter with the *item ID*.
- You can't run stored procedures or triggers across multiple logical partitions.

Request Units in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB supports many APIs, such as SQL, MongoDB, Cassandra, Gremlin, and Table. Each API has its own set of database operations. These operations range from simple point reads and writes to complex queries. Each database operation consumes system resources based on the complexity of the operation.

The cost of all database operations is normalized by Azure Cosmos DB and is expressed by Request Units (or RUs, for short). Request unit is a performance currency abstracting the system resources such as CPU, IOPS, and memory that are required to perform the database operations supported by Azure Cosmos DB.

The cost to do a point read (i.e. fetching a single item by its ID and partition key value) for a 1 KB item is 1 Request Unit (or 1 RU). All other database operations are similarly assigned a cost using RUs. No matter which API you use to interact with your Azure Cosmos container, costs are always measured by RUs. Whether the database operation is a write, point read, or query, costs are always measured in RUs.

The following image shows the high-level idea of RUs:

To manage and plan capacity, Azure Cosmos DB ensures that the number of RUs for a given database operation over a given dataset is deterministic. You can examine the response header to track the number of RUs that are consumed by any database operation. When you understand the factors that affect RU charges and your application's throughput requirements, you can run your application cost effectively.

The type of Azure Cosmos account you're using determines the way consumed RUs get charged. There are 3 modes in which you can create an account:

1. **Provisioned throughput mode**: In this mode, you provision the number of RUs for your application on a per-second basis in increments of 100 RUs per second. To scale the

provisioned throughput for your application, you can increase or decrease the number of RUs at any time in increments or decrements of 100 RUs. You can make your changes either programmatically or by using the Azure portal. You are billed on an hourly basis for the amount of RUs per second you have provisioned. To learn more, see the Provisioned throughput article.

You can provision throughput at two distinct granularities:

- **Containers**: For more information, see Provision throughput on an Azure Cosmos container.
- **Databases**: For more information, see Provision throughput on an Azure Cosmos database.

2. **Serverless mode**: In this mode, you don't have to provision any throughput when creating resources in your Azure Cosmos account. At the end of your billing period, you get billed for the amount of Request Units that has been consumed by your database operations. To learn more, see the Serverless throughput article.

3. **Autoscale mode**: In this mode, you can automatically and instantly scale the throughput (RU/s) of your database or container based on it's usage, without impacting the availability, latency, throughput, or performance of the workload. This mode is well suited for mission-critical workloads that have variable or unpredictable traffic patterns, and require SLAs on high performance and scale. To learn more, see the autoscale throughput article.

Request Unit considerations

While you estimate the number of RUs consumed by your workload, consider the following factors:

- **Item size**: As the size of an item increases, the number of RUs consumed to read or write the item also increases.

- **Item indexing**: By default, each item is automatically indexed. Fewer RUs are consumed if you choose not to index some of your items in a container.

- **Item property count**: Assuming the default indexing is on all properties, the number of RUs consumed to write an item increases as the item property count increases.

- **Indexed properties**: An index policy on each container determines which properties are indexed by default. To reduce the RU consumption for write operations, limit the number of indexed properties.

- **Data consistency**: The strong and bounded staleness consistency levels consume approximately two times more RUs while performing read operations when compared to that of other relaxed consistency levels.

- **Type of reads**: Point reads cost significantly fewer RUs than queries.

- **Query patterns**: The complexity of a query affects how many RUs are consumed for an operation. Factors that affect the cost of query operations include:

  - The number of query results
  - The number of predicates
  - The nature of the predicates
  - The number of user-defined functions
  - The size of the source data
  - The size of the result set
  - Projections

The same query on the same data will always costs the same number of RUs on repeated executions.

- **Script usage**: As with queries, stored procedures and triggers consume RUs based on the complexity of the operations that are performed. As you develop your application, inspect the request charge header to better understand how much RU capacity each operation consumes.

Request units and multiple regions

If you provision *'R'* RUs on a Cosmos container (or database), Cosmos DB ensures that *'R'* RUs are available in *each* region associated with your Cosmos account. You can't selectively assign RUs to a specific region. The RUs provisioned on a Cosmos container (or database) are provisioned in all the regions associated with your Cosmos account.

Assuming that a Cosmos container is configured with *'R'* RUs and there are *'N'* regions associated with the Cosmos account, the total RUs available globally on the container = *R* x *N*.

Your choice of consistency model also affects the throughput. You can get approximately 2x read throughput for the more relaxed consistency levels (e.g., *session*, *consistent prefix* and *eventual* consistency) compared to stronger consistency levels (e.g., *bounded staleness* or *strong* consistency).

Introduction to provisioned throughput in Azure Cosmos DB

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB allows you to set provisioned throughput on your databases and containers. There are two types of provisioned throughput, standard (manual) or autoscale. This article gives an overview of how provisioned throughput works.

An Azure Cosmos database is a unit of management for a set of containers. A database consists of a set of schema-agnostic containers. An Azure Cosmos container is the unit of scalability for both throughput and storage. A container is horizontally partitioned across a set of machines within an Azure region and is distributed across all Azure regions associated with your Azure Cosmos account.

With Azure Cosmos DB, you can provision throughput at two granularities:

- Azure Cosmos containers
- Azure Cosmos databases

Set throughput on a container

The throughput provisioned on an Azure Cosmos container is exclusively reserved for that container. The container receives the provisioned throughput all the time. The provisioned throughput on a container is financially backed by SLAs. To learn how to configure standard (manual) throughput on a container, see Provision throughput on an Azure Cosmos container. To learn how to configure autoscale throughput on a container, see Provision autoscale throughput.

Setting provisioned throughput on a container is the most frequently used option. You can elastically scale throughput for a container by provisioning any amount of throughput by using Request Units (RUs).

The throughput provisioned for a container is evenly distributed among its physical partitions, and assuming a good partition key that distributes the logical partitions evenly among the physical partitions, the throughput is also distributed evenly across all the logical partitions of the container. You cannot selectively specify the throughput for logical partitions. Because one or more logical partitions of a container are hosted by a physical partition, the physical partitions belong exclusively to the container and support the throughput provisioned on the container.

If the workload running on a logical partition consumes more than the throughput that was allocated to the underlying physical partition, it's possible that your operations will be rate-limited. What is known as a *hot partition* occurs when one logical partition has disproportionately more requests than other partition key values.

When rate-limiting occurs, you can either increase the provisioned throughput for the entire container or retry the operations. You also should ensure that you choose a partition key that evenly distributes storage and request volume. For more information about partitioning, see Partitioning and horizontal scaling in Azure Cosmos DB.

We recommend that you configure throughput at the container granularity when you want predictable performance for the container.

The following image shows how a physical partition hosts one or more logical partitions of a container:

Set throughput on a database

When you provision throughput on an Azure Cosmos database, the throughput is shared across all the containers (called shared database containers) in the database. An exception is if you specified a provisioned throughput on specific containers in the database. Sharing the database-level provisioned throughput among its containers is analogous to hosting a database on a cluster of machines. Because all containers within a database share the resources available on a machine, you naturally do not get predictable performance on any specific container. To learn how to configure provisioned throughput on a database, see Configure provisioned throughput on an Azure Cosmos database. To learn how to configure autoscale throughput on a database, see Provision autoscale throughput.

Because all containers within the database share the provisioned throughput, Azure Cosmos DB doesn't provide any predictable throughput guarantees for a particular container in that database. The portion of the throughput that a specific container can receive is dependent on:

- The number of containers.
- The choice of partition keys for various containers.
- The distribution of the workload across various logical partitions of the containers.

We recommend that you configure throughput on a database when you want to share the throughput across multiple containers, but don't want to dedicate the throughput to any particular container.

The following examples demonstrate where it's preferred to provision throughput at the database level:

- Sharing a database's provisioned throughput across a set of containers is useful for a multitenant application. Each user can be represented by a distinct Azure Cosmos container.

- Sharing a database's provisioned throughput across a set of containers is useful when you migrate a NoSQL database, such as MongoDB or Cassandra, hosted on a cluster of VMs or from on-premises physical servers to Azure Cosmos DB. Think of the provisioned throughput configured on your Azure Cosmos database as a logical equivalent, but more cost-effective and elastic, to that of the compute capacity of your MongoDB or Cassandra cluster.

All containers created inside a database with provisioned throughput must be created with a partition key. At any given point in time, the throughput allocated to a container within a database is distributed across all the logical partitions of that container. When you have containers that share provisioned throughput configured on a database, you can't selectively apply the throughput to a specific container or a logical partition.

If the workload on a logical partition consumes more than the throughput that's allocated to a specific logical partition, your operations are rate-limited. When rate-limiting occurs, you can either increase the throughput for the entire database or retry the operations. For more information on partitioning, see Logical partitions.

Containers in a shared throughput database share the throughput (RU/s) allocated to that database. With standard (manual) provisioned throughput, you can have up to 25 containers with a minimum of 400 RU/s on the database. With autoscale provisioned throughput, you can have up to 25 containers in a database with autoscale max 4000 RU/s (scales between 400 - 4000 RU/s).

> **NOTE**
>
> In February 2020, we introduced a change that allows you to have a maximum of 25 containers in a shared throughput database, which better enables throughput sharing across the containers. After the first 25 containers, you can add more containers to the database only if they are provisioned with dedicated throughput, which is separate from the shared throughput of the database.
> If your Azure Cosmos DB account already contains a shared throughput database with >=25 containers, the account and all other accounts in the same Azure subscription are exempt from this change. Please contact product support if you have feedback or questions.

If your workloads involve deleting and recreating all the collections in a database, it is recommended that you drop the empty database and recreate a new database prior to collection creation. The following image shows how a physical partition can host one or more logical partitions that belong to different containers within a database:

Set throughput on a database and a container

You can combine the two models. Provisioning throughput on both the database and the container is allowed. The following example shows how to provision standard (manual) provisioned throughput on an Azure Cosmos database and a container:

- You can create an Azure Cosmos database named *Z* with standard (manual) provisioned throughput of *"K"* RUs.
- Next, create five containers named *A*, *B*, *C*, *D*, and *E* within the database. When creating container B, make sure to enable **Provision dedicated throughput for this container** option and explicitly configure *"P"* RUs of provisioned throughput on this container. You can configure shared and dedicated throughput only when creating the database and container.

- The *"K"* RUs throughput is shared across the four containers *A*, *C*, *D*, and *E*. The exact amount of throughput available to *A*, *C*, *D*, or *E* varies. There are no SLAs for each individual container's throughput.
- The container named *B* is guaranteed to get the *"P"* RUs throughput all the time. It's backed by SLAs.

> **NOTE**
>
> A container with provisioned throughput cannot be converted to shared database container. Conversely a shared database container cannot be converted to have a dedicated throughput.

Update throughput on a database or a container

After you create an Azure Cosmos container or a database, you can update the provisioned throughput. There is no limit on the maximum provisioned throughput that you can configure on the database or the container.

Current provisioned throughput

You can retrieve the provisioned throughput of a container or a database in the Azure portal or by using the SDKs:

- Container.ReadThroughputAsync on the .NET SDK.
- CosmosContainer.readThroughput on the Java SDK.

The response of those methods also contains the minimum provisioned throughput for the container or database:

- ThroughputResponse.MinThroughput on the .NET SDK.
- ThroughputResponse.getMinThroughput() on the Java SDK.

The actual minimum RU/s may vary depending on your account configuration. But generally it's the maximum of:

- 400 RU/s
- Current storage in GB * 10 RU/s (unless your container or database contains more than 1 TB of data, see our high storage / low throughput program)
- Highest RU/s provisioned on the database or container / 100

Changing the provisioned throughput

You can scale the provisioned throughput of a container or a database through the Azure portal or by using the SDKs:

- Container.ReplaceThroughputAsync on the .NET SDK.
- CosmosContainer.replaceThroughput on the Java SDK.

If you are **reducing the provisioned throughput**, you will be able to do it up to the minimum.

If you are **increasing the provisioned throughput**, most of the time, the operation is instantaneous. There are however, cases where the operation can take longer time due to the system tasks to provision the required resources. In this case, an attempt to modify the provisioned throughput while this operation is in progress will yield an HTTP 423 response with an error message explaining that another scaling operation is in progress.

> **NOTE**
>
> If you are planning for a very large ingestion workload that will require a big increase in provisioned throughput, keep in mind that the scaling operation has no SLA and, as mentioned in the previous paragraph, it can take a long time when the increase is large. You might want to plan ahead and start the scaling before the workload starts and use the below methods to check progress.

You can programmatically check the scaling progress by reading the current provisioned throughput and using:

- ThroughputResponse.IsReplacePending on the .NET SDK.
- ThroughputResponse.isReplacePending() on the Java SDK.

You can use Azure Monitor metrics to view the history of provisioned throughput (RU/s) and storage on a resource.

High storage / low throughput program

As described in the Current provisioned throughput section above, the minimum throughput you can provision on a container or database depends on a number of factors. One of them is the amount of data currently stored, as Azure Cosmos DB enforces a minimum throughput of 10 RU/s per GB of storage.

This can be a concern in situations where you need to store large amounts of data, but have low throughput requirements in comparison. To better accommodate these scenarios, Azure Cosmos DB has introduced a **"high storage / low throughput" program** that decreases the RU/s per GB constraint on eligible accounts.

You currently need to have at least 1 container or shared-throughput database containing more than 1 TB of data in your account to be eligible. To join this program and assess your full eligibility, all you have to do is to fill this survey. The Azure Cosmos DB team will then follow up and proceed with your onboarding.

Comparison of models

This table shows a comparison between provisioning standard (manual) throughput on a database vs. on a container.

PARAMETER	STANDARD (MANUAL) THROUGHPUT ON A DATABASE	STANDARD (MANUAL) THROUGHPUT ON A CONTAINER	AUTOSCALE THROUGHPUT ON A DATABASE	AUTOSCALE THROUGHPUT ON A CONTAINER

PARAMETER	STANDARD (MANUAL) THROUGHPUT ON A DATABASE	STANDARD (MANUAL) THROUGHPUT ON A CONTAINER	AUTOSCALE THROUGHPUT ON A DATABASE	AUTOSCALE THROUGHPUT ON A CONTAINER
Entry point (minimum RU/s)	400 RU/s. Can have up to 25 containers with no RU/s minimum per container.	400	Autoscale between 400 - 4000 RU/s. Can have up to 25 containers with no RU/s minimum per container.	Autoscale between 400 - 4000 RU/s.
Minimum RU/s per container	--	400	--	Autoscale between 400 - 4000 RU/s
Maximum RUs	Unlimited, on the database.	Unlimited, on the container.	Unlimited, on the database.	Unlimited, on the container.
RUs assigned or available to a specific container	No guarantees. RUs assigned to a given container depend on the properties. Properties can be the choice of partition keys of containers that share the throughput, the distribution of the workload, and the number of containers.	All the RUs configured on the container are exclusively reserved for the container.	No guarantees. RUs assigned to a given container depend on the properties. Properties can be the choice of partition keys of containers that share the throughput, the distribution of the workload, and the number of containers.	All the RUs configured on the container are exclusively reserved for the container.
Maximum storage for a container	Unlimited.	Unlimited	Unlimited	Unlimited
Maximum throughput per logical partition of a container	10K RU/s	10K RU/s	10K RU/s	10K RU/s
Maximum storage (data + index) per logical partition of a container	20 GB	20 GB	20 GB	20 GB

Create Azure Cosmos containers and databases with autoscale throughput

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

In Azure Cosmos DB, you can configure either standard (manual) or autoscale provisioned throughput on your databases and containers. Autoscale provisioned throughput in Azure Cosmos DB allows you to **scale the throughput (RU/s) of your database or container automatically and instantly**. The throughput is scaled based on the usage, without impacting the availability, latency, throughput, or performance of the workload.

Autoscale provisioned throughput is well suited for mission-critical workloads that have variable or unpredictable traffic patterns, and require SLAs on high performance and scale. This article describes the benefits and use cases of autoscale provisioned throughput.

Benefits of autoscale

Azure Cosmos databases and containers that are configured with autoscale provisioned throughput have the following benefits:

- **Simple:** Autoscale removes the complexity of managing RU/s with custom scripting or manually scaling capacity.
- **Scalable:** Databases and containers automatically scale the provisioned throughput as needed. There is no disruption to client connections, applications, or impact to Azure Cosmos DB SLAs.
- **Cost-effective:** Autoscale helps optimize your RU/s usage and cost usage by scaling down when not in use. You only pay for the resources that your workloads need on a per-hour basis. Of all hours in a month, if you set autoscale max RU/s(Tmax) and use the full amount Tmax for 66% of the hours or less, you'll save with autoscale. To learn more, see the how to choose between standard (manual) and autoscale provisioned throughput article.
- **Highly available:** Databases and containers using autoscale use the same globally distributed, fault-tolerant, highly available Azure Cosmos DB backend to ensure data durability and high availability.

Use cases of autoscale

The use cases of autoscale include:

- **Variable or unpredictable workloads:** When your workloads have variable or unpredictable spikes in usage, autoscale helps by automatically scaling up and down based on usage. Examples include retail websites that have different traffic patterns depending on seasonality; IOT workloads that have spikes at various times during the day; line of business applications that see peak usage a few times a month or year, and more. With autoscale, you no longer need to manually provision for peak or average capacity.
- **New applications:** If you're developing a new application and not sure about the throughput (RU/s) you need, autoscale makes it easy to get started. You can start with the autoscale entry point of 400 - 4000 RU/s, monitor your usage, and determine the right RU/s over time.
- **Infrequently used applications:** If you have an application that's only used for a few hours several times a day, week, or month — such as a low-volume application/web/blog site — autoscale adjusts the

capacity to handle peak usage and scales down when it's over.

- **Development and test workloads:** If you or your team use Azure Cosmos databases and containers during work hours, but don't need them on nights or weekends, autoscale helps save cost by scaling down to a minimum when not in use.
- **Scheduled production workloads/queries:** If you have a series of scheduled requests, operations, or queries that you want to run during idle periods, you can do that easily with autoscale. When you need to run the workload, the throughput will automatically scale to what's needed and scale down afterward.

Building a custom solution to these problems not only requires an enormous amount of time, but also introduces complexity in your application's configuration or code. Autoscale enables the above scenarios out of the box and removes the need for custom or manual scaling of capacity.

How autoscale provisioned throughput works

When configuring containers and databases with autoscale, you specify the maximum throughput `Tmax` required. Azure Cosmos DB scales the throughput `T` such `0.1*Tmax <= T <= Tmax`. For example, if you set the maximum throughput to 20,000 RU/s, the throughput will scale between 2000 to 20,000 RU/s. Because scaling is automatic and instantaneous, at any point in time, you can consume up to the provisioned `Tmax` with no delay.

Each hour, you will be billed for the highest throughput `T` the system scaled to within the hour.

The entry point for autoscale maximum throughput `Tmax` starts at 4000 RU/s, which scales between 400 - 4000 RU/s. You can set `Tmax` in increments of 1000 RU/s and change the value at any time.

Enable autoscale on existing resources

Use the Azure portal to enable autoscale on an existing database or container. You can switch between autoscale and standard (manual) provisioned throughput at any time. See this documentation for more information. Currently, for all APIs, you can only use the Azure portal to enable autoscale on existing resources.

Throughput and storage limits for autoscale

For any value of `Tmax`, the database or container can store a total of `0.01 * Tmax GB`. After this amount of storage is reached, the maximum RU/s will be automatically increased based on the new storage value, with no impact to your application.

For example, if you start with a maximum RU/s of 50,000 RU/s (scales between 5000 - 50,000 RU/s), you can store up to 500 GB of data. If you exceed 500 GB - e.g. storage is now 600 GB, the new maximum RU/s will be 60,000 RU/s (scales between 6000 - 60,000 RU/s).

When you use database level throughput with autoscale, you can have the first 25 containers share an autoscale maximum RU/s of 4000 (scales between 400 - 4000 RU/s), as long as you don't exceed 40 GB of storage. See this documentation for more information.

Comparison – containers configured with manual vs autoscale throughput

For more detail, see this documentation on how to choose between standard (manual) and autoscale throughput.

	CONTAINERS WITH STANDARD (MANUAL) THROUGHPUT	CONTAINERS WITH AUTOSCALE THROUGHPUT
Provisioned throughput (RU/s)	Manually provisioned.	Automatically and instantaneously scaled based on the workload usage patterns.
Rate-limiting of requests/operations (429)	May happen, if consumption exceeds provisioned capacity.	Will not happen if you consume RU/s within the autoscale throughput range that you've set.
Capacity planning	You have to do capacity planning and provision the exact throughput you need.	The system automatically takes care of capacity planning and capacity management.
Pricing	You pay for the manually provisioned RU/s per hour, using the standard (manual) RU/s per hour rate.	You pay per hour for the highest RU/s the system scaled up to within the hour. For single write region accounts, you pay for the RU/s used on an hourly basis, using the autoscale RU/s per hour rate. For accounts with multiple write regions, there is no extra charge for autoscale. You pay for the throughput used on hourly basis using the same multi-region write RU/s per hour rate.
Best suited for workload types	Predictable and stable workloads	Unpredictable and variable workloads

Frequently asked questions about autoscale provisioned throughput in Azure Cosmos DB

11/2/2020 • 11 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

With autoscale provisioned throughput, Azure Cosmos DB will automatically manage and scale the RU/s of your database or container based on usage. This article answers commonly asked questions about autoscale.

Frequently asked questions

What is the difference between "autopilot" and "autoscale" in Azure Cosmos DB?

"Autoscale" or "autoscale provisioned throughput" is the updated name for the feature, previously known as "autopilot." With the current release of autoscale, we've added new features, including the ability to set custom max RU/s and programmatic support.

What happens to databases or containers created in the previous autopilot tier model?

Resources that were created with the previous tier model are automatically supported with the new autoscale custom maximum RU/s model. The upper bound of the tier becomes the new maximum RU/s, which results in the same scale range.

For example, if you previously selected the tier that scaled between 400 to 4000 RU/s, the database or container will now show as having a maximum RU/s of 4000 RU/s, which scales between 400 to 4000 RU/s. From here, you can change the maximum RU/s to a custom value to suit your workload.

How quickly will autoscale scale up based on spikes in traffic?

With autoscale, the system scales the throughput (RU/s) `T` up or down within the `0.1 * Tmax` and `Tmax` range, based on incoming traffic. Because the scaling is automatic and instantaneous, at any point in time, you can consume up to the provisioned `Tmax` with no delay.

How do I determine what RU/s the system is currently scaled to?

Use Azure Monitor metrics to monitor both the provisioned autoscale max RU/s and the current throughput (RU/s) the system is scaled to.

What is the pricing for autoscale?

Each hour, you will be billed for the highest throughput `T` the system scaled to within the hour. If your resource had no requests during the hour or did not scale beyond `0.1 * Tmax`, you will be billed for the minimum of `0.1 * Tmax`. Refer to the Azure Cosmos DB pricing page for details.

How does autoscale show up on my bill?

In single write region accounts, the autoscale rate per 100 RU/s is 1.5x the rate of standard (manual) provisioned throughput. On your bill, you will see the existing standard provisioned throughput meter. The quantity of this meter will be multiplied by 1.5. For example, if the highest RU/s the system scaled to within an hour was 6000 RU/s, you'd be billed 60 * 1.5 = 90 units of the meter for that hour.

In accounts with multiple write regions, the autoscale rate per 100 RU/s is the same as the rate for standard (manual) provisioned multiple write region throughput. On your bill, you will see the existing multiple write regions meter. Since the rates are the same, if you use autoscale, you'll see the same quantity as with standard throughput.

Does autoscale work with reserved capacity?

Yes. When you purchase reserved capacity for accounts with multiple write regions, the reservation discount for autoscale resources is applied to your meter usage at a ratio of 1.5 * the ratio of the specific region.

Multi-write region reserved capacity works the same for autoscale and standard (manual) provisioned throughput. See Azure Cosmos DB reserved capacity

Does autoscale work with free tier?

Yes. In free tier, you can use autoscale throughput on a container. Support for autoscale shared throughput databases with custom max RU/s is not yet available. See how free tier billing works with autoscale.

Is autoscale supported for all APIs?

Yes, autoscale is supported for all APIs: Core (SQL), Gremlin, Table, Cassandra, and API for MongoDB.

Is autoscale supported for multi-region write accounts?

Yes. The max RU/s are available in each region that is added to the Azure Cosmos DB account.

How do I enable autoscale on new databases or containers?

See this article on how to enable autoscale.

Can I enable autoscale on an existing database or a container?

Yes. You can also switch between autoscale and standard (manual) provisioned throughput as needed. Currently, for all APIs, you can only use the Azure portal to do these operations.

How does the migration between autoscale and standard (manual) provisioned throughput work?

Conceptually, changing the throughput type is a two-stage process. First, you send a request to change the throughput settings to use either autoscale or manual provisioned throughput. In both cases, the system will automatically determine and set an initial RU/s value, based on the current throughput settings and storage. During this step, no user-provided RU/s value will be accepted. Then, after the update is complete, you can change the RU/s to suit your workload.

Migration from standard (manual) provisioned throughput to autoscale

For a container, use the following formula to estimate the initial autoscale max RU/s: `MAX(4000, current manual provisioned RU/s, maximum RU/s ever provisioned / 10, storage in GB * 100)`, rounded to the nearest 1000 RU/s. The actual initial autoscale max RU/s may vary depending on your account configuration.

Example #1: Suppose you have a container with 10,000 RU/s manual provisioned throughput, and 25 GB of storage. When you enable autoscale, the initial autoscale max RU/s will be: 10,000 RU/s, which will scale between 1000 - 10,000 RU/s.

Example #2: Suppose you have a container with 50,000 RU/s manual provisioned throughput, and 2500 GB of storage. When you enable autoscale, the initial autoscale max RU/s will be: 250,000 RU/s, which will scale between 25,000 - 250,000 RU/s.

Migration from autoscale to standard (manual) provisioned throughput

The initial manual provisioned throughput will be equal to the current autoscale max RU/s.

Example: Suppose you have an autoscale database or container with max RU/s of 20,000 RU/s (scales between 2000 - 20,000 RU/s). When you update to use manual provisioned throughput, the initial throughput will be 20,000 RU/s.

Is there Azure CLI or PowerShell support to manage databases or containers with autoscale?

Currently, you can only create and manage resources with autoscale from the Azure portal, .NET V3 SDK, Java V4 SDK, and Azure Resource Manager. Support in Azure CLI, PowerShell, and other SDKs is not yet available.

Is autoscale supported for shared throughput databases?

Yes, autoscale is supported for shared throughput databases. To enable this feature, select autoscale and the **Provision throughput** option when creating the database.

What is the number of allowed containers per shared throughput database when autoscale is enabled?

Azure Cosmos DB enforces a maximum of 25 containers in a shared throughput database, which applies to databases with autoscale or standard (manual) throughput.

What is the impact of autoscale on database consistency level?

There is no impact of the autoscale on consistency level of the database. See the consistency levels article for more information regarding available consistency levels.

What is the storage limit associated with each max RU/s option?

The storage limit in GB for each max RU/s is: Max RU/s of database or container / 100. For example, if the max RU/s is 20,000 RU/s, the resource can support 200 GB of storage. See the autoscale limits article for the available max RU/s and storage options.

What happens if I exceed the storage limit associated with my max throughput?

If the storage limit associated with the max throughput of the database or container is exceeded, Azure Cosmos DB will automatically increase the max throughput to the next highest RU/s that can support that level of storage.

For example, if you start with a max RU/s of 50,000 RU/s (scales between 5000 - 50,000 RU/s), you can store up to 500 GB of data. If you exceed 500 GB - e.g. storage is now 600 GB, the new maximum RU/s will be 60,000 RU/s (scales between 6000 - 60,000 RU/s).

Can I change the max RU/s on the database or container?

Yes. See this article on how to change the max RU/s. When you change the max RU/s, depending on the requested value, this can be an asynchronous operation that may take some time to complete (may be up to 4-6 hours, depending on the RU/s selected)

Increasing the max RU/s

When you send a request to increase the max RU/s `Tmax`, depending on the max RU/s selected, the service provisions more resources to support the higher max RU/s. While this is happening, your existing workload and operations will not be affected. The system will continue to scale your database or container between the previous `0.1*Tmax` to `Tmax` until the new scale range of `0.1*Tmax_new` to `Tmax_new` is ready.

Lowering the max RU/s

When you lower the max RU/s, the minimum value you can set it to is: `MAX(4000, highest max RU/s ever provisioned / 10, current storage in GB * 100)`, rounded to the nearest 1000 RU/s.

Example #1: Suppose you have an autoscale container with max RU/s of 20,000 RU/s (scales between 2000 - 20,000 RU/s) and 50 GB of storage. The lowest, minimum value you can set max RU/s to is: MAX(4000, 20,000 / 10, **50 * 100**) = 5000 RU/s (scales between 500 - 5000 RU/s).

Example #2: Suppose you have an autoscale container with max RU/s of 100,000 RU/s and 100 GB of storage. Now, you scale max RU/s up to 150,000 RU/s (scales between 15,000 - 150,000 RU/s). The lowest, minimum value you can now set max RU/s to is: MAX(4000, **150,000 / 10**, 100 * 100) = 15,000 RU/s (scales between 1500 - 15,000 RU/s).

For a shared throughput database, when you lower the max RU/s, the minimum value you can set it to is:

```
MAX(4000, highest max RU/s ever provisioned / 10, current storage in GB * 100, 4000 + (MAX(Container count - 25, 0) * 1000))
```

, rounded to the nearest 1000 RU/s.

The above formulas and examples relate to the minimum autoscale max RU/s you can set, and is distinct from the `0.1 * Tmax` to `Tmax` range the system automatically scales between. No matter what the max RU/s is, the system

will always scale between `0.1 * Tmax` to `Tmax`.

How does TTL work with autoscale?

With autoscale, TTL operations do not affect the scaling of RU/s. Any RUs consumed due to TTL are not part of the billed RU/s of the autoscale container.

For example, suppose you have an autoscale container with 400 – 4000 RU/s:

- Hour 1: T=0: The container has no usage (no TTL or workload requests). The billable RU/s is 400 RU/s.
- Hour 1: T=1: TTL is enabled.
- Hour 1: T=2: The container starts getting requests, which consume 1000 RU in 1 second. There are also 200 RUs worths of TTL that need to happen. The billable RU/s is still 1000 RU/s. Regardless of when the TTLs occur, they will not affect the autoscale scaling logic.

What is the mapping between the max RU/s and physical partitions?

When you first select the max RU/s, Azure Cosmos DB will provision: Max RU/s / 10,000 RU/s = # of physical partitions. Each physical partition can support up to 10,000 RU/s and 50 GB of storage. As storage size grows, Azure Cosmos DB will automatically split the partitions to add more physical partitions to handle the storage increase, or increase the max RU/s if storage exceeds the associated limit.

The max RU/s of the database or container is divided evenly across all physical partitions. So, the total throughput any single physical partition can scale to is: Max RU/s of database or container / # physical partitions.

What happens if incoming requests exceed the max RU/s of the database or container?

If the overall consumed RU/s exceeds the max RU/s of the database or container, requests that exceed the max RU/s will be throttled and return a 429 status code. Requests that result in over 100% normalized utilization will also be throttled. Normalized utilization is defined as the max of the RU/s utilization across all physical partitions. For example, suppose your max throughput is 20,000 RU/s and you have two physical partitions, P_1 and P_2, each capable of scaling to 10,000 RU/s. In a given second, if P_1 has used 6000 RUs, and P_2 8000 RUs, the normalized utilization is MAX(6000 RU / 10,000 RU, 8000 RU / 10,000 RU) = 0.8.

> **NOTE**
>
> The Azure Cosmos DB client SDKs and data import tools (Azure Data Factory, bulk executor library) automatically retry on 429s, so occasional 429s are fine. A sustained high number of 429s may indicate you need to increase the max RU/s or review your partitioning strategy for a hot partition.

Is it still possible to see 429s (throttling/rate limiting) when autoscale is enabled?

Yes. It is possible to see 429s in two scenarios. First, when the overall consumed RU/s exceeds the max RU/s of the database or container, the service will throttle requests accordingly.

Second, if there is a hot partition, i.e. a logical partition key value that has a disproportionately higher amount of requests compared to other partition key values, it is possible for the underlying physical partition to exceed its RU/s budget. As a best practice, to avoid hot partitions, choose a good partition key that results in an even distribution of both storage and throughput.

For example, if you select the 20,000 RU/s max throughput option and have 200 GB of storage, with four physical partitions, each physical partition can be autoscaled up to 5000 RU/s. If there was a hot partition on a particular logical partition key, you will see 429s when the underlying physical partition it resides in exceeds 5000 RU/s, i.e. exceeds 100% normalized utilization.

Azure Cosmos DB serverless (Preview)

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

> **IMPORTANT**
> Azure Cosmos DB serverless is currently in preview. This preview version is provided without a Service Level Agreement and is not recommended for production workloads. For more information, see Supplemental terms of use for Microsoft Azure previews.

Azure Cosmos DB serverless lets you use your Azure Cosmos account in a consumption-based fashion where you are only charged for the Request Units consumed by your database operations and the storage consumed by your data. There is no minimum charge involved when using Azure Cosmos DB in serverless mode.

> **IMPORTANT**
> Do you have any feedback about serverless? We want to hear it! Feel free to drop a message to the Azure Cosmos DB serverless team: azurecosmosdbserverless@service.microsoft.com.

When using Azure Cosmos DB, every database operation has a cost expressed in Request Units. How you are charged for this cost depends on the type of Azure Cosmos account you are using:

- In provisioned throughput mode, you have to commit to a certain amount of throughput (expressed in Request Units per second) that is provisioned on your databases and containers. The cost of your database operations is then deducted from the number of Request Units available every second. At the end of your billing period, you get billed for the amount of throughput you have provisioned.
- In serverless mode, you don't have to provision any throughput when creating containers in your Azure Cosmos account. At the end of your billing period, you get billed for the number of Request Units that were consumed by your database operations.

Use-cases

Azure Cosmos DB serverless best fits scenarios where you expect:

- **Low, intermittent and unpredictable traffic**: Because provisioning capacity in such situations isn't required and may be cost-prohibitive
- **Moderate performance**: Because serverless containers have specific performance characteristics

For these reasons, Azure Cosmos DB serverless should be considered for the following types of workload:

- Development
- Testing
- Prototyping
- Proof of concept
- Non-critical application with light traffic

See the how to choose between provisioned throughput and serverless article for more guidance on how to

choose the offer that best fits your use-case.

Using serverless resources

Serverless is a new Azure Cosmos account type, which means that you have to choose between **provisioned throughput** and **serverless** when creating a new account. You must create a new serverless account to get started with serverless. During the preview release, the only supported way to create a new serverless account is by using the Azure portal. Migrating existing accounts to/from serverless mode is not currently supported.

Any container that is created in a serverless account is a serverless container. Serverless containers expose the same capabilities as containers created in provisioned throughput mode, so you read, write and query your data the exact same way. However serverless accounts and containers also have specific characteristics:

> **IMPORTANT**
>
> Some of these limitations may be eased or removed when serverless becomes generally available and **your feedback** will help us decide! Reach out and tell us more about your serverless experience: azurecosmosdbserverless@service.microsoft.com.

- A serverless account can only run in a single Azure region. It is not possible to add additional Azure regions to a serverless account after you create it.
- It is not possible to enable the Synapse Link preview feature on a serverless account.
- Provisioning throughput is not required on serverless containers, so the following statements are applicable:
  - You can't pass any throughput when creating a serverless container and doing so returns an error.
  - You can't read or update the throughput on a serverless container and doing so returns an error.
  - You can't create a shared throughput database in a serverless account and doing so returns an error.
- Serverless containers can store a maximum of 50 GB of data and indexes.

Monitoring your consumption

If you have used Azure Cosmos DB in provisioned throughput mode before, you will find that serverless is more cost-effective when your traffic doesn't justify provisioned capacity. The trade-off is that your costs will become less predictable because you are billed based on the number of requests your database has processed. Because of that, it's important to keep an eye on your current consumption.

When browsing the **Metrics** pane of your account, you will find a chart named **Request Units consumed** under the **Overview** tab. This chart shows how many Request Units your account has consumed:

You can find the same chart when using Azure Monitor, as described here. Note that Azure Monitor lets you

setup alerts, which can be used to notify you when your Request Unit consumption has passed a certain threshold.

Performance

Serverless resources yield specific performance characteristics that are different from what provisioned throughput resources deliver:

- **Availability**: After the serverless offer becomes generally available, the availability of serverless containers will be covered by a Service Level Agreement (SLA) of 99.9% when Availability Zones (zone redundancy) aren't used. The SLA is 99.99% when Availability Zones are used.
- **Latency**: After the serverless offer becomes generally available, the latency of serverless containers will be covered by a Service Level Objective (SLO) of 10 milliseconds or less for point-reads and 30 milliseconds or less for writes. A point-read operation consists in fetching a single item by its ID and partition key value.
- **Burstability**: After the serverless offer becomes generally available, the burstability of serverless containers will be covered by a Service Level Objective (SLO) of 95%. This means the maximum burstability can be attained at least 95% of the time.

> **NOTE**
>
> As any Azure preview, Azure Cosmos DB serverless is excluded from Service Level Agreements (SLA). The performance characteristics mentioned above are provided as a preview of what this offer will deliver when generally available.

How to choose between standard (manual) and autoscale provisioned throughput

11/2/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB supports two types or offers of provisioned throughput: standard (manual) and autoscale. Both throughput types are suitable for mission-critical workloads that require high performance and scale, and are backed by the same Azure Cosmos DB SLAs on throughput, availability, latency, and consistency.

This article describes how to choose between standard (manual) and autoscale provisioned throughput for your workload.

Overview of provisioned throughput types

Before diving into the difference between standard (manual) and autoscale, it's important to first understand how provisioned throughput works in Azure Cosmos DB.

When you use provisioned throughput, you set the throughput, measured in request units per second (RU/s) required for your workload. The service provisions the capacity needed to support the throughput requirements. Database operations against the service, such as reads, writes, and queries consume some amount of request units (RUs). Learn more about request units.

The following table shows a high-level comparison between standard (manual) and autoscale.

DESCRIPTION	STANDARD (MANUAL)	AUTOSCALE
Best suited for	Workloads with steady or predictable traffic	Workloads with variable or unpredictable traffic. See use cases of autoscale.
How it works	You provision a set amount of RU/s `T` that is static over time, unless you manually change them. Each second, you can use up to `T` RU/s throughput. For example, if you set standard (manual) 400 RU/s, the throughput will stay at 400 RU/s.	You set the highest, or maximum RU/s `Tmax` you don't want the system to exceed. The system automatically scales the throughput `T` such that `0.1* Tmax <= T <= Tmax`. For example, if you set autoscale maximum RU/s of 4000 RU/s, the system will scale between 400 - 4000 RU/s.

DESCRIPTION	STANDARD (MANUAL)	AUTOSCALE
When to use it	You want to manually manage your throughput capacity (RU/s) and scale yourself. You have high, consistent utilization of provisioned RU/s. Of all hours in a month, if you set provisioned RU/s `T` and use the full amount for 66% of the hours or more, it's estimated you'll save with standard (manual) provisioned RU/s. This is based on a comparison between setting `T` in standard (manual) and the same amount `Tmax` in autoscale.	You want Azure Cosmos DB to manage your throughput capacity (RU/s) and scale, based on usage. You have RU/s usage that is variable or hard to predict. Of all hours in a month, if you set autoscale max RU/s `Tmax` and use the full amount `Tmax` for 66% of the hours or less, it's estimated you'll save with autoscale. This is based on a comparison between setting autoscale `Tmax` and the same amount `T` in standard (manual) throughput.
Billing model	Billing is done on a per-hour basis for the RU/s provisioned, regardless of how many RUs were consumed. Example: • Provision 400 RU/s • Hour 1: no requests • Hour 2: 400 RU/s worth of requests For both hours 1 and 2, you'll be billed 400 RU/s for both hours at the standard (manual) rates.	Billing is done on a per-hour basis, for the highest RU/s the system scaled to in the hour. Example: • Provision autoscale max RU/s of 4000 RU/s (scales between 400 - 4000 RU/s) • Hour 1: system scaled up to highest value of 3500 RU/s • Hour 2: system scaled down to minimum of 400 RU/s (always 10% of `Tmax`), due to no usage You will be billed for 3500 RU/s in hour 1, and 400 RU/s in hour 2 at the autoscale provisioned throughput rates. The autoscale rate per RU/s is 1.5 * the standard (manual) rate.
What happens if you exceed provisioned RU/s	The RU/s remain static at what is provisioned. Any requests that consume beyond the provisioned RUs in a second will be rate-limited, with a response that recommends a time to wait before retrying. You can manually increase or decrease the RU/s if needed.	The system will scale the RU/s up to the autoscale max RU/s. Any requests that consume beyond the autoscale max RU/s in a second will be rate-limited, with a response that recommends a time to wait before retrying.

Understand your traffic patterns

New applications

If you are building a new application and do not know your traffic pattern yet, you may want to start at the entry point RU/s (or minimum RU/s) to avoid over-provisioning in the beginning. Or, if you have a small application that doesn't need high scale, you may want to provision just the minimum entry point RU/s to optimize cost. For small applications with a low expected traffic, you can also consider the serverless capacity mode.

Whether you plan to use standard (manual) or autoscale, here's what you should consider:

If you provision standard (manual) RU/s at the entry point of 400 RU/s, you won't be able to consume above 400 RU/s, unless you manually change the throughput. You'll be billed for 400 RU/s at the standard (manual)

provisioned throughput rate, per hour.

If you provision autoscale throughput at the entry point of max RU/s of 4000 RU/s, the resource will scale between 400 to 4000 RU/s. Since the autoscale throughput billing rate per RU/s is 1.5x of the standard (manual) rate, for hours where the system has scaled down to the minimum of 400 RU/s, your bill will be higher than if you provisioned 400 RU/s manually. However, with autoscale, at any time, if your application traffic spikes, you can consume up to 4000 RU/s with no user action required. In general, you should weigh the benefit of being able to consume up to the max RU/s at any time with the 1.5x rate of autoscale.

Use the Azure Cosmos DB capacity calculator to estimate your throughput requirements.

Existing applications

If you have an existing application using standard (manual) provisioned throughput, you can use Azure Monitor metrics to determine if your traffic pattern is suitable for autoscale.

First, find the normalized request unit consumption metric of your database or container. Normalized utilization is a measure of how much you are currently using your standard (manual) provisioned throughput. The closer the number is to 100%, the more you are fully using your provisioned RU/s. Learn more about the metric.

Next, determine how the normalized utilization varies over time. Find the highest normalized utilization for each hour. Then, calculate the average normalized utilization across all hours. If you see that your average utilization is less than 66%, consider enabling autoscale on your database or container. In contrast, if the average utilization is greater than 66%, it's recommended to remain on standard (manual) provisioned throughput.

> **TIP**
> If your account is configured to use multi-region writes and has more than one region, the rate per 100 RU/s is the same for both manual and autoscale. This means that enabling autoscale incurs no additional cost regardless of utilization. As a result, it is always recommended to use autoscale with multi-region writes when you have more than one region, to take advantage of the savings from paying only for the RU/s your application scales to. If you have multi-region writes and one region, use the average utilization to determine if autoscale will result in cost savings.

Examples

Let's take a look at two different example workloads and analyze if they are suitable for manual or autoscale throughput. To illustrate the general approach, we'll analyze three hours of history to determine the cost difference between using manual and autoscale. For production workloads, it's recommended to use 7 to 30 days of history (or longer if available) to establish a pattern of RU/s usage.

> **NOTE**
> All the examples shown in this doc are based on the price for an Azure Cosmos account deployed in a non-government region in the US. The pricing and calculation vary depending on the region you are using, see the Azure Cosmos DB pricing page for the latest pricing information.

Assumptions:

- Suppose we currently have manual throughput of 30,000 RU/s.
- Our region is configured with single-region writes, with one region. If we had multiple regions, we would multiply the hourly cost by the number of regions.
- Use public pricing rates for manual ($0.008 USD per 100 RU/s per hour) and autoscale throughput ($0.012 USD per 100 RU/s per hour) in single-region write accounts. See pricing page for details.

Example 1: Variable workload (autoscale recommended)

First, we look at the normalized RU consumption. This workload has variable traffic, with normalized RU consumption ranging from 6% to 100%. There are occasional spikes to 100% that are hard to predict, but many

hours with low utilization.

Let's compare the cost of provisioning 30,000 RU/s manual throughput, versus setting autoscale max RU/s to 30,000 (scales between 3000 - 30,000 RU/s).

Now, let's analyze the history. Suppose we have the utilization described in the following table. The average utilization across these three hours is 39%. Because the normalized RU consumption averages to less than 66%, we save by using autoscale.

Note that in hour 1, when there is 6% usage, autoscale will bill RU/s for 10% of the max RU/s, which is the minimum per hour. Though the cost of autoscale may be higher than manual throughput in certain hours, as long as the average utilization is less than 66% across all hours, autoscale will be cheaper overall.

TIME PERIOD	UTILIZATION	BILLED AUTOSCALE RU/S	OPTION 1: MANUAL 30,000 RU/S	OPTION 2: AUTOSCALE BETWEEN 3000 - 30,000 RU/S
Hour 1	6%	3000	30,000 * 0.008 / 100 = $2.40	3000 * 0.012 / 100 = $0.36
Hour 2	100%	30,000	30,000 * 0.008 / 100 = $2.40	30,000 * 0.012 / 100 = $3.60
Hour 3	11%	3300	30,000 * 0.008 / 100 = $2.40	3300 * 0.012 / 100 = $0.40
Total			$7.20	$4.36 (39% savings)

Example 2: Steady workload (manual throughput recommended)

This workload has steady traffic, with normalized RU consumption ranging from 72% to 100%. With 30,000 RU/s provisioned, this means that we are consuming between 21,600 to 30,000 RU/s.

Let's compare the cost of provisioning 30,000 RU/s manual throughput, versus setting autoscale max RU/s to 30,000 (scales between 3000 - 30,000 RU/s).

Suppose we have the utilization history as described in the table. Our average utilization across these three hours is 88%. Because the normalized RU consumption averages to greater than 66%, we save by using manual throughput.

In general, if the average utilization across all 730 hours in one month is greater than 66%, then we'll save by using manual throughput.

TIME PERIOD	UTILIZATION	BILLED AUTOSCALE RU/S	OPTION 1: MANUAL 30,000 RU/S	OPTION 2: AUTOSCALE BETWEEN 3000 - 30,000 RU/S
Hour 1	72%	21,600	30,000 * 0.008 / 100 = $2.40	21600 * 0.012 / 100 = $2.59
Hour 2	93%	28,000	30,000 * 0.008 / 100 = $2.40	28,000 * 0.012 / 100 = $3.36
Hour 3	100%	30,000	30,000 * 0.008 / 100 = $2.40	30,000 * 0.012 / 100 = $3.60
Total			$7.20	$9.55

TIP

With standard (manual) throughput, you can use the normalized utilization metric to estimate the actual RU/s you may use if you switch to autoscale. Multiply the normalized utilization at a point in time by the currently provisioned standard (manual) RU/s. For example, if you have provisioned 5000 RU/s, and the normalized utilization is 90%, the RU/s usage is 0.9 * 5000 = 4500 RU/s. If you see that your traffic pattern is variable, but you are over or under provisioned, you may want to enable autoscale and then change the autoscale max RU/s setting accordingly.

How to calculate average utilization

Autoscale bills for the highest RU/s scaled to in an hour. When analyzing the normalized RU consumption over time, it is important to use the highest utilization per hour when calculating the average.

To calculate the average of the highest utilization across all hours:

1. Set the **Aggregation** on the Noramlized RU Consumption metric to **Max**.
2. Select the **Time granularity** to 1 hour.
3. Navigate to **Chart options**.
4. Select the bar chart option.
5. Under **Share**, select the **Download to Excel** option. From the generated spreadsheet, calculate the average utilization across all hours.

Measure and monitor your usage

Over time, after you've chosen the throughput type, you should monitor your application and make adjustments as needed.

When using autoscale, use Azure Monitor to see the provisioned autoscale max RU/s (**Autoscale Max Throughput**) and the RU/s the system is currently scaled to (**Provisioned Throughput**). Below is an example of a variable or unpredictable workload using autoscale. Note when there isn't any traffic, the system scales the RU/s to the minimum of 10% of the max RU/s, which in this case is 5000 RU/s and 50,000 RU/s, respectively.

> **NOTE**
>
> When you use standard (manual) provisioned throughput, the **Provisioned Throughput** metric refers to what you as a user have set. When you use autoscale throughput, this metric refers to the RU/s the system is currently scaled to.

Next steps

- Use RU calculator to estimate throughput for new workloads.
- Use Azure Monitor to monitor your existing workloads.
- Learn how to provision autoscale throughput on an Azure Cosmos database or container.
- Review the autoscale FAQ.

How to choose between provisioned throughput and serverless

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB is available in two different capacity modes: provisioned throughput and serverless. You can perform the exact same database operations in both modes, but the way you get billed for these operations is radically different. The following video explains the core differences between these modes and how they fit different types of workloads:

Detailed comparison

CRITERIA	PROVISIONED THROUGHPUT	SERVERLESS
Status	Generally available	In preview
Best suited for	Mission-critical workloads requiring predictable performance	Small-to-medium non-critical workloads with light and intermittent traffic
How it works	For each of your containers, you provision some amount of throughput expressed in Request Units per second. Every second, this amount of Request Units is available for your database operations. Provisioned throughput can be updated manually or adjusted automatically with autoscale.	You run your database operations against your containers without having to provision any capacity.
Geo-distribution	Available (unlimited number of Azure regions)	Unavailable (serverless accounts can only run in 1 Azure region)
Maximum storage per container	Unlimited	50 GB
Performance	99.99% to 99.999% availability covered by SLA < 10 ms latency for point-reads and writes covered by SLA 99.99% guaranteed throughput covered by SLA	99.9% to 99.99% availability covered by SLA < 10 ms latency for point-reads and < 30 ms for writes covered by SLO 95% burstability covered by SLO
Billing model	Billing is done on a per-hour basis for the RU/s provisioned, regardless of how many RUs were consumed.	Billing is done on a per-hour basis for the amount of RUs consumed by your database operations.

> **IMPORTANT**
> Some of the serverless limitations may be eased or removed when serverless becomes generally available and **your feedback** will help us decide! Reach out and tell us more about your serverless experience: azurecosmosdbserverless@service.microsoft.com.

Estimating your expected consumption

In some situations, it may be unclear whether provisioned throughput or serverless should be chosen for a given workload. To help with this decision, you can estimate your overall **expected consumption**, that is what's the total number of RUs you may consume over a month (you can estimate this with the help of the table shown here)

Example 1: a workload is expected to burst to a maximum of 500 RU/s and consume a total of 20,000,000 RUs over a month.

- In provisioned throughput mode, you would provision a container with 500 RU/s for a monthly cost of: $0.008 * 5 * 730 = **$29.20**
- In serverless mode, you would pay for the consumed RUs: $0.25 * 20 = **$5.00**

Example 2: a workload is expected to burst to a maximum of 500 RU/s and consume a total of 250,000,000 RUs over a month.

- In provisioned throughput mode, you would provision a container with 500 RU/s for a monthly cost of: $0.008 * 5 * 730 = **$29.20**
- In serverless mode, you would pay for the consumed RUs: $0.25 * 250 = **$62.50**

(these examples are not accounting for the storage cost, which is the same between the two modes)

> **NOTE**
> The costs shown in the previous example are for demonstration purposes only. See the pricing page for the latest pricing information.

Security in Azure Cosmos DB - overview

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

This article discusses database security best practices and key features offered by Azure Cosmos DB to help you prevent, detect, and respond to database breaches.

What's new in Azure Cosmos DB security

Encryption at rest is now available for documents and backups stored in Azure Cosmos DB in all Azure regions. Encryption at rest is applied automatically for both new and existing customers in these regions. There is no need to configure anything; and you get the same great latency, throughput, availability, and functionality as before with the benefit of knowing your data is safe and secure with encryption at rest.

How do I secure my database

Data security is a shared responsibility between you, the customer, and your database provider. Depending on the database provider you choose, the amount of responsibility you carry can vary. If you choose an on-premises solution, you need to provide everything from end-point protection to physical security of your hardware - which is no easy task. If you choose a PaaS cloud database provider such as Azure Cosmos DB, your area of concern shrinks considerably. The following image, borrowed from Microsoft's Shared Responsibilities for Cloud Computing white paper, shows how your responsibility decreases with a PaaS provider like Azure Cosmos DB.

The preceding diagram shows high-level cloud security components, but what items do you need to worry about specifically for your database solution? And how can you compare solutions to each other?

We recommend the following checklist of requirements on which to compare database systems:

- Network security and firewall settings
- User authentication and fine grained user controls
- Ability to replicate data globally for regional failures
- Ability to fail over from one data center to another
- Local data replication within a data center
- Automatic data backups
- Restoration of deleted data from backups
- Protect and isolate sensitive data
- Monitoring for attacks
- Responding to attacks
- Ability to geo-fence data to adhere to data governance restrictions
- Physical protection of servers in protected data centers
- Certifications

And although it may seem obvious, recent large-scale database breaches remind us of the simple but critical importance of the following requirements:

- Patched servers that are kept up-to-date
- HTTPS by default/TLS encryption
- Administrative accounts with strong passwords

How does Azure Cosmos DB secure my database

Let's look back at the preceding list - how many of those security requirements does Azure Cosmos DB provide? Every single one.

Let's dig into each one in detail.

SECURITY REQUIREMENT	AZURE COSMOS DB'S SECURITY APPROACH
Network security	Using an IP firewall is the first layer of protection to secure your database. Azure Cosmos DB supports policy driven IP-based access controls for inbound firewall support. The IP-based access controls are similar to the firewall rules used by traditional database systems, but they are expanded so that an Azure Cosmos database account is only accessible from an approved set of machines or cloud services. Learn more in Azure Cosmos DB firewall support article. Azure Cosmos DB enables you to enable a specific IP address (168.61.48.0), an IP range (168.61.48.0/8), and combinations of IPs and ranges. All requests originating from machines outside this allowed list are blocked by Azure Cosmos DB. Requests from approved machines and cloud services then must complete the authentication process to be given access control to the resources. You can use virtual network service tags to achieve network isolation and protect your Azure Cosmos DB resources from the general Internet. Use service tags in place of specific IP addresses when you create security rules. By specifying the service tag name (for example, AzureCosmosDB) in the appropriate source or destination field of a rule, you can allow or deny the traffic for the corresponding service.

SECURITY REQUIREMENT	AZURE COSMOS DB'S SECURITY APPROACH
Authorization	Azure Cosmos DB uses hash-based message authentication code (HMAC) for authorization. Each request is hashed using the secret account key, and the subsequent base-64 encoded hash is sent with each call to Azure Cosmos DB. To validate the request, the Azure Cosmos DB service uses the correct secret key and properties to generate a hash, then it compares the value with the one in the request. If the two values match, the operation is authorized successfully and the request is processed, otherwise there is an authorization failure and the request is rejected. You can use either a primary key, or a resource token allowing fine-grained access to a resource such as a document. Learn more in Securing access to Azure Cosmos DB resources.
Users and permissions	Using the primary key for the account, you can create user resources and permission resources per database. A resource token is associated with a permission in a database and determines whether the user has access (read-write, read-only, or no access) to an application resource in the database. Application resources include container, documents, attachments, stored procedures, triggers, and UDFs. The resource token is then used during authentication to provide or deny access to the resource. Learn more in Securing access to Azure Cosmos DB resources.
Active directory integration (Azure RBAC)	You can also provide or restrict access to the Cosmos account, database, container, and offers (throughput) using Access control (IAM) in the Azure portal. IAM provides role-based access control and integrates with Active Directory. You can use built in roles or custom roles for individuals and groups. See Active Directory integration article for more information.
Global replication	Azure Cosmos DB offers turnkey global distribution, which enables you to replicate your data to any one of Azure's world-wide datacenters with the click of a button. Global replication lets you scale globally and provide low-latency access to your data around the world. In the context of security, global replication ensures data protection against regional failures. Learn more in Distribute data globally.
Regional failovers	If you have replicated your data in more than one data center, Azure Cosmos DB automatically rolls over your operations should a regional data center go offline. You can create a prioritized list of failover regions using the regions in which your data is replicated. Learn more in Regional Failovers in Azure Cosmos DB.

SECURITY REQUIREMENT	AZURE COSMOS DB'S SECURITY APPROACH
Local replication	Even within a single data center, Azure Cosmos DB automatically replicates data for high availability giving you the choice of consistency levels. This replication guarantees a99.99% availability SLA for all single region accounts and all multi-region accounts with relaxed consistency, and 99.999% read availability on all multi-region database accounts.
Automated online backups	Azure Cosmos databases are backed up regularly and stored in a geo redundant store. Learn more in Automatic online backup and restore with Azure Cosmos DB.
Restore deleted data	The automated online backups can be used to recover data you may have accidentally deleted up to ~30 days after the event. Learn more in Automatic online backup and restore with Azure Cosmos DB
Protect and isolate sensitive data	All data in the regions listed in What's new? is now encrypted at rest. Personal data and other confidential data can be isolated to specific container and read-write, or read-only access can be limited to specific users.
Monitor for attacks	By using audit logging and activity logs, you can monitor your account for normal and abnormal activity. You can view what operations were performed on your resources, who initiated the operation, when the operation occurred, the status of the operation, and much more as shown in the screenshot following this table.
Respond to attacks	Once you have contacted Azure support to report a potential attack, a 5-step incident response process is kicked off. The goal of the 5-step process is to restore normal service security and operations as quickly as possible after an issue is detected and an investigation is started. Learn more in Microsoft Azure Security Response in the Cloud.
Geo-fencing	Azure Cosmos DB ensures data governance for sovereign regions (for example, Germany, China, US Gov).
Protected facilities	Data in Azure Cosmos DB is stored on SSDs in Azure's protected data centers. Learn more in Microsoft global datacenters
HTTPS/SSL/TLS encryption	All connections to Azure Cosmos DB support HTTPS. Azure Cosmos DB also supports TLS 1.2. It is possible to enforce a minimum TLS version server-side. To do so, please contact azurecosmosdbtls@service.microsoft.com.

SECURITY REQUIREMENT	AZURE COSMOS DB'S SECURITY APPROACH
Encryption at rest	All data stored into Azure Cosmos DB is encrypted at rest. Learn more in Azure Cosmos DB encryption at rest
Patched servers	As a managed database, Azure Cosmos DB eliminates the need to manage and patch servers, that's done for you, automatically.
Administrative accounts with strong passwords	It's hard to believe we even need to mention this requirement, but unlike some of our competitors, it's impossible to have an administrative account with no password in Azure Cosmos DB. Security via TLS and HMAC secret based authentication is baked in by default.
Security and data protection certifications	For the most up-to-date list of certifications see the overall Azure Compliance site as well as the latest Azure Compliance Document with all certifications (search for Cosmos). For a more focused read check out the April 25, 2018 post [Azure #CosmosDB: Secure, private, compliant that includes SOCS 1/2 Type 2, HITRUST, PCI DSS Level 1, ISO 27001, HIPAA, FedRAMP High, and many others.

The following screenshot shows how you can use audit logging and activity logs to monitor your account:

Primary keys

Primary keys provide access to all the administrative resources for the database account. Primary keys:

- Provide access to accounts, databases, users, and permissions.
- Cannot be used to provide granular access to containers and documents.

- Are created during the creation of an account.
- Can be regenerated at any time.

Each account consists of two primary keys: a primary key and secondary key. The purpose of dual keys is so that you can regenerate, or roll keys, providing continuous access to your account and data.

In addition to the two primary keys for the Cosmos DB account, there are two read-only keys. These read-only keys only allow read operations on the account. Read-only keys do not provide access to read permissions resources.

Primary, secondary, read only, and read-write primary keys can be retrieved and regenerated using the Azure portal. For instructions, see View, copy, and regenerate access keys.

Next steps

For more information about primary keys and resource tokens, see Securing access to Azure Cosmos DB data.

For more information about audit logging, see Azure Cosmos DB diagnostic logging.

For more information about Microsoft certifications, see Azure Trust Center.

Data encryption in Azure Cosmos DB

11/2/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Encryption at rest is a phrase that commonly refers to the encryption of data on nonvolatile storage devices, such as solid state drives (SSDs) and hard disk drives (HDDs). Cosmos DB stores its primary databases on SSDs. Its media attachments and backups are stored in Azure Blob storage, which is generally backed up by HDDs. With the release of encryption at rest for Cosmos DB, all your databases, media attachments, and backups are encrypted. Your data is now encrypted in transit (over the network) and at rest (nonvolatile storage), giving you end-to-end encryption.

As a PaaS service, Azure Cosmos DB is very easy to use. Because all user data stored in Azure Cosmos DB is encrypted at rest and in transport, you don't have to take any action. Another way to put this is that encryption at rest is "on" by default. There are no controls to turn it off or on. Azure Cosmos DB uses AES-256 encryption on all regions where the account is running. We provide this feature while we continue to meet our availability and performance SLAs. Data stored in your Azure Cosmos account is automatically and seamlessly encrypted with keys managed by Microsoft (service-managed keys). Optionally, you can choose to add a second layer of encryption with your own keys as described in the customer-managed keys article.

Implementation of encryption at rest for Azure Cosmos DB

Encryption at rest is implemented by using a number of security technologies, including secure key storage systems, encrypted networks, and cryptographic APIs. Systems that decrypt and process data have to communicate with systems that manage keys. The diagram shows how storage of encrypted data and the management of keys is separated.

The basic flow of a user request is as follows:

- The user database account is made ready, and storage keys are retrieved via a request to the Management Service Resource Provider.
- A user creates a connection to Cosmos DB via HTTPS/secure transport. (The SDKs abstract the details.)
- The user sends a JSON document to be stored over the previously created secure connection.
- The JSON document is indexed unless the user has turned off indexing.
- Both the JSON document and index data are written to secure storage.
- Periodically, data is read from the secure storage and backed up to the Azure Encrypted Blob Store.

Frequently asked questions

Q: How much more does Azure Storage cost if Storage Service Encryption is enabled?

A: There is no additional cost.

Q: Who manages the encryption keys?

A: The keys are managed by Microsoft.

Q: How often are encryption keys rotated?

A: Microsoft has a set of internal guidelines for encryption key rotation, which Cosmos DB follows. The specific guidelines are not published. Microsoft does publish the Security Development Lifecycle (SDL), which is seen as a subset of internal guidance and has useful best practices for developers.

Q: Can I use my own encryption keys?

A: Yes, this feature is now available for new Azure Cosmos DB accounts and this should be done at the time of account creation. Please go through Customer-managed Keys document for more information.

Q: What regions have encryption turned on?

A: All Azure Cosmos DB regions have encryption turned on for all user data.

Q: Does encryption affect the performance latency and throughput SLAs?

A: There is no impact or changes to the performance SLAs now that encryption at rest is enabled for all existing and new accounts. You can read more on the SLA for Cosmos DB page to see the latest guarantees.

Q: Does the local emulator support encryption at rest?

A: The emulator is a standalone dev/test tool and does not use the key management services that the managed Cosmos DB service uses. Our recommendation is to enable BitLocker on drives where you are storing sensitive emulator test data. The emulator supports changing the default data directory as well as using a well-known location.

Next steps

- You can choose to add a second layer of encryption with your own keys, to learn more, see the customer-managed keys article.
- For an overview of Cosmos DB security and the latest improvements, see Azure Cosmos database security.
- For more information about Microsoft certifications, see the Azure Trust Center.

Virtual network service tags

12/4/2020 • 9 minutes to read • Edit Online

A service tag represents a group of IP address prefixes from a given Azure service. Microsoft manages the address prefixes encompassed by the service tag and automatically updates the service tag as addresses change, minimizing the complexity of frequent updates to network security rules.

You can use service tags to define network access controls on network security groups or Azure Firewall. Use service tags in place of specific IP addresses when you create security rules. By specifying the service tag name, such as **ApiManagement**, in the appropriate *source* or *destination* field of a rule, you can allow or deny the traffic for the corresponding service.

You can use service tags to achieve network isolation and protect your Azure resources from the general Internet while accessing Azure services that have public endpoints. Create inbound/outbound network security group rules to deny traffic to/from **Internet** and allow traffic to/from **AzureCloud** or other available service tags of specific Azure services.

Network Security Group (NSG)				
Action	Name	Source	Destination	Port
Allow	AllowStorage	VirtualNetwork	**Storage**	Any
Allow	AllowSQL	VirtualNetwork	**Sql.EastUS**	Any
Deny	DenyAllOutBound	Any	Any	Any

Available service tags

The following table includes all the service tags available for use in network security group rules.

The columns indicate whether the tag:

- Is suitable for rules that cover inbound or outbound traffic.
- Supports regional scope.
- Is usable in Azure Firewall rules.

By default, service tags reflect the ranges for the entire cloud. Some service tags also allow more granular control by restricting the corresponding IP ranges to a specified region. For example, the service tag **Storage** represents Azure Storage for the entire cloud, but **Storage.WestUS** narrows the range to only the storage IP address ranges from the WestUS region. The following table indicates whether each service tag supports such regional scope.

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
ActionGroup	Action Group.	Inbound	No	No
ApiManagement	Management traffic for Azure API Management-dedicated deployments. *Note:* This tag represents the Azure API Management service endpoint for control plane per region. This enables customers to perform management operations on the APIs, Operations, Policies, NamedValues configured on the API Management service.	Inbound	Yes	Yes
ApplicationInsightsAvailability	Application Insights Availability.	Inbound	No	No
AppConfiguration	App Configuration.	Outbound	No	No
AppService	Azure App Service. This tag is recommended for outbound security rules to web apps and Function apps.	Outbound	Yes	Yes
AppServiceManagement	Management traffic for deployments dedicated to App Service Environment.	Both	No	Yes
AzureActiveDirectory	Azure Active Directory.	Outbound	No	Yes
AzureActiveDirectoryDomainServices	Management traffic for deployments dedicated to Azure Active Directory Domain Services.	Both	No	Yes
AzureAdvancedThreatProtection	Azure Advanced Threat Protection.	Outbound	No	No

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
AzureBackup	Azure Backup. *Note:* This tag has a dependency on the **Storage** and **AzureActiveDirectory** tags.	Outbound	No	Yes
AzureBotService	Azure Bot Service.	Outbound	No	No
AzureCloud	All datacenter public IP addresses.	Outbound	Yes	Yes
AzureCognitiveSearch	Azure Cognitive Search. This tag or the IP addresses covered by this tag can be used to grant indexers secure access to data sources. Refer to the indexer connection documentation for more details. *Note*: The IP of the search service is not included in the list of IP ranges for this service tag and **also needs to be added** to the IP firewall of data sources.	Inbound	No	No
AzureConnectors	Azure Logic Apps connectors for probe/back-end connections.	Inbound	Yes	Yes
AzureContainerRegistry	Azure Container Registry.	Outbound	Yes	Yes
AzureCosmosDB	Azure Cosmos DB.	Outbound	Yes	Yes
AzureDatabricks	Azure Databricks.	Both	No	No
AzureDataExplorerManagement	Azure Data Explorer Management.	Inbound	No	No
AzureDataLake	Azure Data Lake Storage Gen1.	Outbound	No	Yes
AzureDevSpaces	Azure Dev Spaces.	Outbound	No	No

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
AzureDevOps	Azure Dev Ops. *Note: This tag is not currently configurable via Azure Portal*	Inbound	No	Yes
AzureDigitalTwins	Azure Digital Twins. *Note:* This tag or the IP addresses covered by this tag can be used to restrict access to endpoints configured for event routes. *This tag is not currently configurable via Azure Portal*	Inbound	No	Yes
AzureEventGrid	Azure Event Grid.	Both	No	No
AzureFrontDoor.Frontend **AzureFrontDoor.Backend** **AzureFrontDoor.FirstParty**	Azure Front Door.	Both	No	No
AzureInformationProtection	Azure Information Protection. *Note:* This tag has a dependency on the **AzureActiveDirectory**, **AzureFrontDoor.Frontend** and **AzureFrontDoor.FirstParty** tags.	Outbound	No	No
AzureIoTHub	Azure IoT Hub.	Outbound	No	No
AzureKeyVault	Azure Key Vault. *Note:* This tag has a dependency on the **AzureActiveDirectory** tag.	Outbound	Yes	Yes

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
AzureLoadBalancer	The Azure infrastructure load balancer. The tag translates to the virtual IP address of the host (168.63.129.16) where the Azure health probes originate. This only includes probe traffic, not real traffic to your backend resource. If you're not using Azure Load Balancer, you can override this rule.	Both	No	No
AzureMachineLearning	Azure Machine Learning.	Both	No	Yes
AzureMonitor	Log Analytics, Application Insights, AzMon, and custom metrics (GiG endpoints). *Note:* For Log Analytics, this tag has a dependency on the **Storage** tag.	Outbound	No	Yes
AzureOpenDatasets	Azure Open Datasets. *Note:* This tag has a dependency on the **AzureFrontDoor.Frontend** and **Storage** tag.	Outbound	No	No
AzurePlatformDNS	The basic infrastructure (default) DNS service. You can use this tag to disable the default DNS. Be cautious when you use this tag. We recommend that you read Azure platform considerations. We also recommend that you perform testing before you use this tag.	Outbound	No	No

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
AzurePlatformIMDS	Azure Instance Metadata Service (IMDS), which is a basic infrastructure service. You can use this tag to disable the default IMDS. Be cautious when you use this tag. We recommend that you read Azure platform considerations. We also recommend that you perform testing before you use this tag.	Outbound	No	No
AzurePlatformLKM	Windows licensing or key management service. You can use this tag to disable the defaults for licensing. Be cautious when you use this tag. We recommend that you read Azure platform considerations. We also recommend that you perform testing before you use this tag.	Outbound	No	No
AzureResourceManager	Azure Resource Manager.	Outbound	No	No
AzureSignalR	Azure SignalR.	Outbound	No	No
AzureSiteRecovery	Azure Site Recovery. *Note:* This tag has a dependency on the **AzureActiveDirectory**, **AzureKeyVault**, **EventHub**,**GuestAndHybridManagement** and **Storage** tags.	Outbound	No	No

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
AzureTrafficManager	Azure Traffic Manager probe IP addresses. For more information on Traffic Manager probe IP addresses, see Azure Traffic Manager FAQ.	Inbound	No	Yes
BatchNodeManagement	Management traffic for deployments dedicated to Azure Batch.	Both	No	Yes
CognitiveServicesManagement	The address ranges for traffic for Azure Cognitive Services.	Both	No	No
DataFactory	Azure Data Factory	Both	No	No
DataFactoryManagement	Management traffic for Azure Data Factory.	Outbound	No	No
Dynamics365ForMarketingEmail	The address ranges for the marketing email service of Dynamics 365.	Outbound	Yes	No
EventHub	Azure Event Hubs.	Outbound	Yes	Yes
GatewayManager	Management traffic for deployments dedicated to Azure VPN Gateway and Application Gateway.	Inbound	No	No
GuestAndHybridManagement	Azure Automation and Guest Configuration.	Outbound	No	Yes
HDInsight	Azure HDInsight.	Inbound	Yes	No
Internet	The IP address space that's outside the virtual network and reachable by the public internet. The address range includes the Azure-owned public IP address space.	Both	No	No
LogicApps	Logic Apps.	Both	No	No

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
LogicAppsManagement	Management traffic for Logic Apps.	Inbound	No	No
MicrosoftCloudAppSecurity	Microsoft Cloud App Security.	Outbound	No	No
MicrosoftContainerRegistry	Container registry for Microsoft container images. *Note:* This tag has a dependency on the **AzureFrontDoor.FirstParty** tag.	Outbound	Yes	Yes
PowerQueryOnline	Power Query Online.	Both	No	No
ServiceBus	Azure Service Bus traffic that uses the Premium service tier.	Outbound	Yes	Yes
ServiceFabric	Azure Service Fabric. *Note:* This tag represents the Service Fabric service endpoint for control plane per region. This enables customers to perform management operations for their Service Fabric clusters from their VNET (endpoint eg. https://westus.servicefabric.azure.com)	Both	No	No

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
Sql	Azure SQL Database, Azure Database for MySQL, Azure Database for PostgreSQL, and Azure Synapse Analytics. *Note:* This tag represents the service, but not specific instances of the service. For example, the tag represents the Azure SQL Database service, but not a specific SQL database or server. This tag does not apply to SQL managed instance.	Outbound	Yes	Yes
SqlManagement	Management traffic for SQL-dedicated deployments.	Both	No	Yes
Storage	Azure Storage. *Note:* This tag represents the service, but not specific instances of the service. For example, the tag represents the Azure Storage service, but not a specific Azure Storage account.	Outbound	Yes	Yes
StorageSyncService	Storage Sync Service.	Both	No	No
WindowsVirtualDesktop	Windows Virtual Desktop.	Both	No	Yes

TAG	PURPOSE	CAN USE INBOUND OR OUTBOUND?	CAN BE REGIONAL?	CAN USE WITH AZURE FIREWALL?
VirtualNetwork	The virtual network address space (all IP address ranges defined for the virtual network), all connected on-premises address spaces, peered virtual networks, virtual networks connected to a virtual network gateway, the virtual IP address of the host, and address prefixes used on user-defined routes. This tag might also contain default routes.	Both	No	No

NOTE

In the classic deployment model (before Azure Resource Manager), a subset of the tags listed in the previous table are supported. These tags are spelled differently:

CLASSIC SPELLING	EQUIVALENT RESOURCE MANAGER TAG
AZURE_LOADBALANCER	AzureLoadBalancer
INTERNET	Internet
VIRTUAL_NETWORK	VirtualNetwork

NOTE

Service tags of Azure services denote the address prefixes from the specific cloud being used. For example, the underlying IP ranges that correspond to the **Sql** tag value on the Azure Public cloud will be different from the underlying ranges on the Azure China cloud.

NOTE

If you implement a virtual network service endpoint for a service, such as Azure Storage or Azure SQL Database, Azure adds a route to a virtual network subnet for the service. The address prefixes in the route are the same address prefixes, or CIDR ranges, as those of the corresponding service tag.

Service tags on-premises

You can obtain the current service tag and range information to include as part of your on-premises firewall configurations. This information is the current point-in-time list of the IP ranges that correspond to each service tag. You can obtain the information programmatically or via a JSON file download, as described in the following sections.

Use the Service Tag Discovery API (public preview)

You can programmatically retrieve the current list of service tags together with IP address range details:

- REST
- Azure PowerShell
- Azure CLI

> **NOTE**
> While it's in public preview, the Discovery API might return information that's less current than information returned by the JSON downloads. (See the next section.)

Discover service tags by using downloadable JSON files

You can download JSON files that contain the current list of service tags together with IP address range details. These lists are updated and published weekly. Locations for each cloud are:

- Azure Public
- Azure US Government
- Azure China
- Azure Germany

The IP address ranges in these files are in CIDR notation.

> **NOTE**
> A subset of this information has been published in XML files for Azure Public, Azure China, and Azure Germany. These XML downloads will be deprecated by June 30, 2020 and will no longer be available after that date. You should migrate to using the Discovery API or JSON file downloads as described in the previous sections.

Tips

- You can detect updates from one publication to the next by noting increased *changeNumber* values in the JSON file. Each subsection (for example, **Storage.WestUS**) has its own *changeNumber* that's incremented as changes occur. The top level of the file's *changeNumber* is incremented when any of the subsections is changed.
- For examples of how to parse the service tag information (for example, get all address ranges for Storage in WestUS), see the Service Tag Discovery API PowerShell documentation.

Next steps

- Learn how to create a network security group.

Azure role-based access control in Azure Cosmos DB

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB provides built-in Azure role-based access control (Azure RBAC) for common management scenarios in Azure Cosmos DB. An individual who has a profile in Azure Active Directory can assign these Azure roles to users, groups, service principals, or managed identities to grant or deny access to resources and operations on Azure Cosmos DB resources. Role assignments are scoped to control-plane access only, which includes access to Azure Cosmos accounts, databases, containers, and offers (throughput).

Built-in roles

The following are the built-in roles supported by Azure Cosmos DB:

BUILT-IN ROLE	DESCRIPTION
DocumentDB Account Contributor	Can manage Azure Cosmos DB accounts.
Cosmos DB Account Reader	Can read Azure Cosmos DB account data.
Cosmos Backup Operator	Can submit restore request for an Azure Cosmos database or a container. Cannot access any data or use Data Explorer.
Cosmos DB Operator	Can provision Azure Cosmos accounts, databases, and containers. Cannot access any data or use Data Explorer.

IMPORTANT

Azure RBAC support in Azure Cosmos DB applies to control plane operations only. Data plane operations are secured using primary keys or resource tokens. To learn more, see Secure access to data in Azure Cosmos DB

Identity and access management (IAM)

The **Access control (IAM)** pane in the Azure portal is used to configure Azure role-based access control on Azure Cosmos resources. The roles are applied to users, groups, service principals, and managed identities in Active Directory. You can use built-in roles or custom roles for individuals and groups. The following screenshot shows Active Directory integration (Azure RBAC) using access control (IAM) in the Azure portal:

Custom roles

In addition to the built-in roles, users may also create custom roles in Azure and apply these roles to service principals across all subscriptions within their Active Directory tenant. Custom roles provide users a way to create Azure role definitions with a custom set of resource provider operations. To learn which operations are available for building custom roles for Azure Cosmos DB see, Azure Cosmos DB resource provider operations

> **TIP**
>
> Custom roles that need to access data stored within Cosmos DB or use Data Explorer in the Azure portal must have `Microsoft.DocumentDB/databaseAccounts/listKeys/*` action.

Preventing changes from the Azure Cosmos DB SDKs

The Azure Cosmos DB resource provider can be locked down to prevent any changes to resources from a client connecting using the account keys (that is applications connecting via the Azure Cosmos SDK). This also includes changes made from the Azure portal. This feature may be desirable for users who want higher degrees of control and governance for production environments. Preventing changes from the SDK also enables features such as resource locks and diagnostic logs for control plane operations. The clients connecting from Azure Cosmos DB SDK will be prevented from changing any property for the Azure Cosmos accounts, databases, containers, and throughput. The operations involving reading and writing data to Cosmos containers themselves are not impacted.

When this feature is enabled, changes to any resource can only be made from a user with the right Azure role and Azure Active Directory credentials including Managed Service Identities.

> **WARNING**
>
> Enabling this feature can have impact on your application. Make sure that you understand the impact before enabling it.

Check list before enabling

This setting will prevent any changes to any Cosmos resource from any client connecting using account keys including any Cosmos DB SDK, any tools that connect via account keys, or from the Azure portal. To prevent issues or errors from applications after enabling this feature, check if applications or Azure portal users perform any of the following actions before enabling this feature, including:

- Any change to the Cosmos account including any properties or adding or removing regions.
- Creating, deleting child resources such as databases and containers. This includes resources for other APIs

such as Cassandra, MongoDB, Gremlin, and table resources.

- Updating throughput on database or container level resources.
- Modifying container properties including index policy, TTL and unique keys.
- Modifying stored procedures, triggers or user-defined functions.

If your applications (or users via Azure portal) perform any of these actions they will need to be migrated to execute via ARM Templates, PowerShell, Azure CLI, REST, or Azure Management Library. Note that Azure Management is available in multiple languages.

Set via ARM Template

To set this property using an ARM template, update your existing template or export a new template for your current deployment, then include the `"disableKeyBasedMetadataWriteAccess": true` to the properties for the `databaseAccounts` resources. Below is a basic example of an Azure Resource Manager template with this property setting.

```
{
    {
      "type": "Microsoft.DocumentDB/databaseAccounts",
      "name": "[variables('accountName')]",
      "apiVersion": "2020-04-01",
      "location": "[parameters('location')]",
      "kind": "GlobalDocumentDB",
      "properties": {
        "consistencyPolicy": "[variables('consistencyPolicy')[parameters('defaultConsistencyLevel')]]",
        "locations": "[variables('locations')]",
        "databaseAccountOfferType": "Standard",
        "disableKeyBasedMetadataWriteAccess": true
        }
    }
}
```

> **IMPORTANT**
>
> Make sure you include the other properties for your account and child resources when redploying with this property. Do not deploy this template as is or it will reset all of your account properties.

Set via Azure CLI

To enable using Azure CLI, use the command below:

```
az cosmosdb update  --name [CosmosDBAccountName] --resource-group [ResourceGroupName]  --disable-key-based-metadata-write-access true
```

Set via PowerShell

To enable using Azure PowerShell, use the command below:

```
Update-AzCosmosDBAccount -ResourceGroupName [ResourceGroupName] -Name [CosmosDBAccountName] -DisableKeyBasedMetadataWriteAccess true
```

Next steps

Use Azure Policy to implement governance and controls for Azure Cosmos DB resources

11/2/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Policy helps to enforce organizational governance standards, assess resource compliance, and implement automatic remediation. Common use cases include security, cost management, and configuration consistency.

Azure Policy provides built-in policy definitions. You can create custom policy definitions for scenarios that are not addressed by the built-in policy definitions. See the Azure Policy documentation for more details.

> **IMPORTANT**
>
> Azure Policy is enforced at the resource provider level for Azure services. Cosmos DB SDKs can perform most management operations on database, container and throughput resources that bypass Cosmos DB's resource provider, thus ignoring any policies created using Azure Policy. To ensure enforcement of policies see, Preventing changes from the Azure Cosmos DB SDKs

Assign a built-in policy definition

Policy definitions describe resource compliance conditions and the effect to take if a condition is met. Policy *assignments* are created from policy *definitions*. You can use built-in or custom policy definitions for your Azure Cosmos DB resources. Policy assignments are scoped to an Azure management group, an Azure subscription, or a resource group and they are applied to the resources within the selected scope. Optionally, you can exclude specific resources from the scope.

You can create policy assignments with the Azure portal, Azure PowerShell, Azure CLI, or ARM template.

To create a policy assignment from a built-in policy definition for Azure Cosmos DB, use the steps in create a policy assignment with the Azure portal article.

At the step to select a policy definition, enter `Cosmos DB` in the Search field to filter the list of available built-in policy definitions. Select one of the available built-in policy definitions, and then choose **Select** to continue creating the policy assignment.

> **TIP**
>
> You can also use the built-in policy definition names shown in the **Available Definitions** pane with Azure PowerShell, Azure CLI, or ARM templates to create policy assignments.

Create a custom policy definition

For specific scenarios that are not addressed by built-in policies, you can create a custom policy definition. Later you create a Policy *assignment* from your custom policy *definition*.

Property types and property aliases in policy rules

Use the custom policy definition steps to identify the resource properties and property aliases, which are required to create policy rules.

To identify Azure Cosmos DB specific property aliases, use the namespace `Microsoft.DocumentDB` with one of the methods shown in the custom policy definition steps article.

Use the Azure CLI:

```
# Login first with az login if not using Cloud Shell

# Get Azure Policy aliases for namespace Microsoft.DocumentDB
az provider show --namespace Microsoft.DocumentDB --expand "resourceTypes/aliases" --query
"resourceTypes[].aliases[].name"
```

Use Azure PowerShell:

```
# Login first with Connect-AzAccount if not using Cloud Shell

# Use Get-AzPolicyAlias to list aliases for Microsoft.DocumentDB namespace
(Get-AzPolicyAlias -NamespaceMatch 'Microsoft.DocumentDB').Aliases
```

These commands output the list of property alias names for Azure Cosmos DB property. The following is an excerpt from the output:

```
[
  "Microsoft.DocumentDB/databaseAccounts/sku.name",
  "Microsoft.DocumentDB/databaseAccounts/virtualNetworkRules[*]",
  "Microsoft.DocumentDB/databaseAccounts/virtualNetworkRules[*].id",
  "Microsoft.DocumentDB/databaseAccounts/isVirtualNetworkFilterEnabled",
  "Microsoft.DocumentDB/databaseAccounts/consistencyPolicy.defaultConsistencyLevel",
  "Microsoft.DocumentDB/databaseAccounts/enableAutomaticFailover",
  "Microsoft.DocumentDB/databaseAccounts/Locations",
  "Microsoft.DocumentDB/databaseAccounts/Locations[*]",
  "Microsoft.DocumentDB/databaseAccounts/Locations[*].locationName",
  "..."
]
```

You can use any of these property alias names in the custom policy definition rules.

The following is an example policy definition that checks if an Azure Cosmos DB account is configured for multiple write locations. The custom policy definition includes two rules: one to check for the specific type of property alias, and the second one for the specific property of the type, in this case the field that stores the multiple write location setting. Both rules use the alias names.

```
"policyRule": {
  "if": {
    "allOf": [
      {
        "field": "type",
        "equals": "Microsoft.DocumentDB/databaseAccounts"
      },
      {
        "field": "Microsoft.DocumentDB/databaseAccounts/enableMultipleWriteLocations",
        "notEquals": true
      }
    ]
  },
  "then": {
    "effect": "Audit"
  }
}
```

Custom policy definitions can be used to create policy assignments just like the built-in policy definitions are used.

Policy compliance

After the policy assignments are created, Azure Policy evaluates the resources in the assignment's scope. Each resource's *compliance* with the policy is assessed. The *effect* specified in the policy is then applied to non-compliant resources.

You can review the compliance results and remediation details in the Azure portal or via the Azure CLI or the Azure Monitor logs.

The following screenshot shows two example policy assignments.

One assignment is based on a built-in policy definition, which checks that the Azure Cosmos DB resources are deployed only to the allowed Azure regions. Resource compliance shows policy evaluation outcome (compliant or non-compliant) for in-scope resources.

The other assignment is based on a custom policy definition. This assignment checks that Cosmos DB accounts are configured for multiple write locations.

After the policy assignments are deployed, the compliance dashboard shows evaluation results. Note that this can take up to 30 minutes after deploying a policy assignment. Additionally, policy evaluation scans can be started on-demand immediately after creating policy assignments.

The screenshot shows the following compliance evaluation results for in-scope Azure Cosmos DB accounts:

- Zero of two accounts are compliant with a policy that Virtual Network (VNet) filtering must be configured.
- Zero of two accounts are compliant with a policy that requires the account to be configured for multiple write locations
- Zero of two accounts are compliant with a policy that resources were deployed to allowed Azure regions.

Name	Scope	Compliance state	Resource compliance
Cosmos DB | VNet filtering	[redacted]	Non-compliant	0% (0 out of 2)
Cosmos DB | Multiple Write Locations | Deny	[redacted]	Non-compliant	0% (0 out of 2)
Built-in: Azure Cosmos DB allowed locations	[redacted]	Non-compliant	0% (0 out of 2)

To remediate the non-compliant resources, see how to remediate resources with Azure Policy.

Next steps

- Review sample custom policy definitions for Azure Cosmos DB, including for the multiple write location and VNet filtering policies shown above.
- Create a policy assignment in the Azure portal
- Review Azure Policy built-in policy definitions for Azure Cosmos DB

Azure Policy Regulatory Compliance controls for Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Regulatory Compliance in Azure Policy provides Microsoft created and managed initiative definitions, known as *built-ins*, for the **compliance domains** and **security controls** related to different compliance standards. This page lists the **compliance domains** and **security controls** for Azure Cosmos DB. You can assign the built-ins for a **security control** individually to help make your Azure resources compliant with the specific standard.

The title of each built-in policy definition links to the policy definition in the Azure portal. Use the link in the **Policy Version** column to view the source on the Azure Policy GitHub repo.

> **IMPORTANT**
>
> Each control below is associated with one or more Azure Policy definitions. These policies may help you assess compliance with the control; however, there often is not a one-to-one or complete match between a control and one or more policies. As such, **Compliant** in Azure Policy refers only to the policies themselves; this doesn't ensure you're fully compliant with all requirements of a control. In addition, the compliance standard includes controls that aren't addressed by any Azure Policy definitions at this time. Therefore, compliance in Azure Policy is only a partial view of your overall compliance status. The associations between controls and Azure Policy Regulatory Compliance definitions for these compliance standards may change over time.

Azure Security Benchmark

The Azure Security Benchmark provides recommendations on how you can secure your cloud solutions on Azure. To see how this service completely maps to the Azure Security Benchmark, see the Azure Security Benchmark mapping files.

To review how the available Azure Policy built-ins for all Azure services map to this compliance standard, see Azure Policy Regulatory Compliance - Azure Security Benchmark.

DOMAIN	CONTROL ID	CONTROL TITLE	POLICY (AZURE PORTAL)	POLICY VERSION (GITHUB)
Network Security	1.1	Protect resources using Network Security Groups or Azure Firewall on your Virtual Network	Cosmos DB should use a virtual network service endpoint	1.0.0

HIPAA HITRUST 9.2

To review how the available Azure Policy built-ins for all Azure services map to this compliance standard, see Azure Policy Regulatory Compliance - HIPAA HITRUST 9.2. For more information about this compliance standard, see HIPAA HITRUST 9.2.

DOMAIN	CONTROL ID	CONTROL TITLE	POLICY (AZURE PORTAL)	POLICY VERSION (GITHUB)
Segregation in Networks	0805.01m1Organizational.12 - 01.m	The organization's security gateways (e.g. firewalls) enforce security policies and are configured to filter traffic between domains, block unauthorized access, and are used to maintain segregation between internal wired, internal wireless, and external network segments (e.g., the Internet) including DMZs and enforce access control policies for each of the domains.	Cosmos DB should use a virtual network service endpoint	1.0.0
Segregation in Networks	0806.01m2Organizational.12356 - 01.m	The organizations network is logically and physically segmented with a defined security perimeter and a graduated set of controls, including subnetworks for publicly accessible system components that are logically separated from the internal network, based on organizational requirements; and traffic is controlled based on functionality required and classification of the data/systems based on a risk assessment and their respective security requirements.	Cosmos DB should use a virtual network service endpoint	1.0.0
Segregation in Networks	0894.01m2Organizational.7 - 01.m	Networks are segregated from production-level networks when migrating physical servers, applications or data to virtualized servers.	Cosmos DB should use a virtual network service endpoint	1.0.0

DOMAIN	CONTROL ID	CONTROL TITLE	POLICY	POLICY VERSION
Network Controls	0864.09m2Organizational.12 - 09.m	Usage restrictions and implementation guidance are formally defined for VoIP, including the authorization and monitoring of the service.	Cosmos DB should use a virtual network service endpoint	1.0.0

Azure Security Baseline for Cosmos DB

12/4/2020 • 33 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

The Azure Security Baseline for Cosmos DB contains recommendations that will help you improve the security posture of your deployment.

The baseline for this service is drawn from the Azure Security Benchmark version 1.0, which provides recommendations on how you can secure your cloud solutions on Azure with our best practices guidance.

For more information, see Azure Security Baselines overview.

Network Security

For more information, see Security Control: Network Security.

1.1: Protect resources using Network Security Groups or Azure Firewall on your Virtual Network

Guidance: By using Azure Private Link, you can connect to an Azure Cosmos account via a Private Endpoint. Traffic between your virtual network and the service traverses over the Microsoft backbone network, eliminating exposure from the public Internet. You can also reduce the risk of data exfiltration by configuring a strict set of outbound rules on a network security group (NSG) and associating that NSG with your subnet.

You can also use Service Endpoints to secure your Azure Cosmos account. By enabling a Service Endpoint, you can configure Azure Cosmos accounts to allow access from only a specific subnet of an Azure virtual network. Once the Azure Cosmos DB Service Endpoint is enabled, you can limit access to an Azure Cosmos account with connections from a subnet in a virtual network.

You can also secure the data stored in your Azure Cosmos account by using IP firewalls. Azure Cosmos DB supports IP-based access controls for inbound firewall support. You can set an IP firewall on the Azure Cosmos account by using the Azure portal, Azure Resource Manager templates, or through the Azure CLI or Azure PowerShell.

Azure Private Link Overview: https://docs.microsoft.com/azure/private-link/private-link-overview

How to configure a Private Endpoint for Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/how-to-configure-private-endpoints

How to create a Network Security Group with a Security Config: https://docs.microsoft.com/azure/virtual-network/tutorial-filter-network-traffic

How to configure IP firewall in Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/how-to-configure-firewall

Azure Security Center monitoring: Yes

Responsibility: Customer

1.2: Monitor and log the configuration and traffic of Vnets, Subnets, and NICs

Guidance: Use Azure Security Center and follow network protection recommendations to help secure network resources related to your Azure Cosmos account.

When virtual machines are deployed in the same virtual network as your Azure Cosmos account, you can use a

network security group (NSG) to reduce the risk of data exfiltration. Enable NSG flow logs and send logs into an Azure Storage Account for traffic audits. You may also send NSG flow logs to a Log Analytics workspace and use Traffic Analytics to provide insights into traffic flow in your Azure cloud. Some advantages of Traffic Analytics are the ability to visualize network activity and identify hot spots, identify security threats, understand traffic flow patterns, and pinpoint network misconfigurations.

Understand Network Security provided by Azure Security Center: https://docs.microsoft.com/azure/security-center/security-center-network-recommendations

How to Enable NSG Flow Logs: https://docs.microsoft.com/azure/network-watcher/network-watcher-nsg-flow-logging-portal

How to Enable and use Traffic Analytics: https://docs.microsoft.com/azure/network-watcher/traffic-analytics

Azure Security Center monitoring: Yes

Responsibility: Customer

1.3: Protect critical web applications

Guidance: Use the Cross-Origin Resource Sharing (CORS) feature to enable a web application running under one domain to access resources in another domain. Web browsers implement a security restriction known as same-origin policy that prevents a web page from calling APIs in a different domain. However, CORS provides a secure way to allow the origin domain to call APIs in another domain. After you enable the CORS support for your Azure Cosmos account, only authenticated requests are evaluated to determine whether they are allowed according to the rules you have specified.

Configure Cross-Origin Resource Sharing: https://docs.microsoft.com/azure/cosmos-db/how-to-configure-cross-origin-resource-sharing

Azure Security Center monitoring: Yes

Responsibility: Customer

1.4: Deny communications with known malicious IP addresses

Guidance: Use Advanced Threat Protection (ATP) for Azure Cosmos DB . ATP for Azure Cosmos DB provides an additional layer of security intelligence that detects unusual and potentially harmful attempts to access or exploit Azure Cosmos accounts. This layer of protection allows you to address threats and integrate them with central security monitoring systems.

Enable DDoS Protection Standard on the Virtual Networks associated with your Azure Cosmos DB instances to guard against DDoS attacks. Use Azure Security Center Integrated Threat Intelligence to deny communications with known malicious or unused Internet IP addresses.

How to configure Azure Cosmos DB Advanced Threat Protection: https://docs.microsoft.com/azure/cosmos-db/cosmos-db-advanced-threat-protection

How to configure DDoS protection: https://docs.microsoft.com/azure/virtual-network/manage-ddos-protection

Understand Azure Security Center Integrated Threat Intelligence: https://docs.microsoft.com/azure/security-center/security-center-alerts-service-layer

Azure Security Center monitoring: Yes

Responsibility: Customer

1.5: Record network packets and flow logs

Guidance: Enable network security group (NSG) flow logs and send logs into a storage account for traffic audit. You can send NSG flow logs to a Log Analytics workspace and use Traffic Analytics to provide insights into traffic flow in your Azure cloud. Some advantages of Traffic Analytics are the ability to visualize network activity and

identify hot spots, identify security threats, understand traffic flow patterns, and pinpoint network misconfigurations.

How to Enable NSG Flow Logs: https://docs.microsoft.com/azure/network-watcher/network-watcher-nsg-flow-logging-portal

How to Enable and use Traffic Analytics: https://docs.microsoft.com/azure/network-watcher/traffic-analytics

Azure Security Center monitoring: Yes

Responsibility: Customer

1.6: Deploy network based intrusion detection/intrusion prevention systems (IDS/IPS)

Guidance: Use Advanced Threat Protection (ATP) for Azure Cosmos DB. ATP for Azure Cosmos DB provides an additional layer of security intelligence that detects unusual and potentially harmful attempts to access or exploit Azure Cosmos accounts. This layer of protection allows you to address threats and integrate them with central security monitoring systems.

How to configure Cosmos DB Advanced Threat Protection: https://docs.microsoft.com/azure/cosmos-db/cosmos-db-advanced-threat-protection

Azure Security Center monitoring: Yes

Responsibility: Customer

1.7: Manage traffic to web applications

Guidance: Not applicable; recommendation is intended for web applications running on Azure App Service or compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

1.8: Minimize complexity and administrative overhead of network security rules

Guidance: For resources that need access to your Azure Cosmos account, use Virtual Network service tags to define network access controls on network security groups or Azure Firewall. You can use service tags in place of specific IP addresses when creating security rules. By specifying the service tag name (e.g., AzureCosmosDB) in the appropriate source or destination field of a rule, you can allow or deny the traffic for the corresponding service. Microsoft manages the address prefixes encompassed by the service tag and automatically updates the service tag as addresses change.

For more information about using service tags: https://docs.microsoft.com/azure/virtual-network/service-tags-overview

Azure Security Center monitoring: Not applicable

Responsibility: Customer

1.9: Maintain standard security configurations for network devices

Guidance: Define and implement standard security configurations for network resources with Azure Policy. Use Azure Policy aliases in the "Microsoft.DocumentDB" and "Microsoft.Network" namespaces to create custom policies to audit or enforce the network configuration of your Azure Cosmos DB instances. You may also make use of built-in policy definitions for Azure Cosmos DB, such as:

- Deploy Advanced Threat Protection for Cosmos DB Accounts
- Cosmos DB should use a virtual network service endpoint

You may also use Azure Blueprints to simplify large-scale Azure deployments by packaging key environment

artifacts, such as Azure Resource Manager templates, Azure role-based access control (Azure RBAC), and policies in a single blueprint definition. You can easily apply the blueprint to new subscriptions, environments, and fine-tune control and management through versioning.

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

How to create an Azure Blueprint: https://docs.microsoft.com/azure/governance/blueprints/create-blueprint-portal

Azure Security Center monitoring: Not applicable

Responsibility: Customer

1.10: Document traffic configuration rules

Guidance: Use tags for network resources associated with your Azure Cosmos DB deployment in order to logically organize them into a taxonomy.

How to create and use tags: https://docs.microsoft.com/azure/azure-resource-manager/resource-group-using-tags

Azure Security Center monitoring: Not applicable

Responsibility: Customer

1.11: Use automated tools to monitor network resource configurations and detect changes

Guidance: Use Azure Activity Log to monitor network resource configurations and detect changes for network resources related to your Azure Cosmos DB instances. Create alerts within Azure Monitor that will trigger when changes to critical network resources take place.

How to view and retrieve Azure Activity Log events: https://docs.microsoft.com/azure/azure-monitor/platform/activity-log-view

How to create alerts in Azure Monitor: https://docs.microsoft.com/azure/azure-monitor/platform/alerts-activity-log

Azure Security Center monitoring: Not applicable

Responsibility: Customer

Logging and Monitoring

For more information, see Security Control: Logging and Monitoring.

2.1: Use approved time synchronization sources

Guidance: Microsoft maintains the time source used for Azure resources such as Azure Cosmos DB for timestamps in the logs.

Azure Security Center monitoring: Not applicable

Responsibility: Microsoft

2.2: Configure central security log management

Guidance: Ingest logs via Azure Monitor to aggregate security data generated by Azure Cosmos DB. Within the Azure Monitor, use Log Analytics workspace(s) to query and perform analytics, and use storage accounts for long-term/archival storage. Alternatively, you may enable, and on-board data to Azure Sentinel or a third-party Security Incident and Event Management (SIEM).

How to enable diagnostic logs for Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/logging

How to onboard Azure Sentinel: https://docs.microsoft.com/azure/sentinel/quickstart-onboard

Azure Security Center monitoring: Currently not available

Responsibility: Customer

2.3: Enable audit logging for Azure resources

Guidance: Enable diagnostic settings for Azure Cosmos DB and send the logs to a Log Analytics workspace or storage account. Diagnostic settings in Azure Cosmos DB are used to collect resource logs. These logs are captured per request and they are also referred to as "data plane logs". Some examples of the data plane operations include delete, insert, and read. You may also enable Azure Activity Log Diagnostic Settings and send them to the same Log Analytics Workspace.

How to enable Diagnostic Settings for Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/logging

How to enable Diagnostic Settings for Azure Activity Log: https://docs.microsoft.com/azure/azure-monitor/platform/diagnostic-settings-legacy

Azure Security Center monitoring: Currently not available

Responsibility: Customer

2.4: Collect security logs from operating systems

Guidance: Not applicable; this recommendation is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

2.5: Configure security log storage retention

Guidance: In Azure Monitor, set the log retention period for Log Analytics workspaces associated with your Azure Cosmos DB instances according to your organization's compliance regulations.

How to set log retention parameters: https://docs.microsoft.com/azure/azure-monitor/platform/manage-cost-storage#change-the-data-retention-period

Azure Security Center monitoring: Not applicable

Responsibility: Customer

2.6: Monitor and review Logs

Guidance: You can perform queries in Log Analytics a workspace to search terms, identify trends, analyze patterns, and provide many other insights based on the Azure Cosmos DB logs that you gathered.

How to perform queries for Azure Cosmos DB in Log Analytics Workspaces: https://docs.microsoft.com/azure/cosmos-db/monitor-cosmos-db

Azure Security Center monitoring: Not applicable

Responsibility: Customer

2.7: Enable alerts for anomalous activity

Guidance: In Azure Security Center, enable Advanced Threat Protection for Azure Cosmos DB to monitor anomalous activities in security logs and events. Enable diagnostic settings in Azure Cosmos DB and send logs to a Log Analytics workspace.

You can also onboard your Log Analytics workspace to Azure Sentinel as it provides a security orchestration automated response (SOAR) solution. This allows for playbooks (automated solutions) to be created and used to remediate security issues. Additionally, you can create custom log alerts in your Log Analytics workspace using Azure Monitor.

List of threat protection alerts for Azure Cosmos DB: https://docs.microsoft.com/azure/security-center/alerts-

reference#alerts-azurecosmos

How to onboard Azure Sentinel: https://docs.microsoft.com/azure/sentinel/quickstart-onboard

Create, view, and manage log alerts using Azure Monitor: https://docs.microsoft.com/azure/azure-monitor/platform/alerts-log

Azure Security Center monitoring: Yes

Responsibility: Customer

2.8: Centralize anti-malware logging

Guidance: Not applicable; Azure Cosmos DB does not process or produce anti-malware related logs.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

2.9: Enable DNS query logging

Guidance: Not applicable; Azure Cosmos DB does not process or produce DNS-related logs.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

2.10: Enable command-line audit logging

Guidance: Not applicable; this recommendation is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

Identity and Access Control

For more information, see Security Control: Identity and Access Control.

3.1: Maintain an inventory of administrative accounts

Guidance: You can use the Identity and Access control (IAM) pane in the Azure portal to configure Azure role-based access control (Azure RBAC) and maintain inventory on Azure Cosmos DB resources. The roles are applied to users, groups, service principals, and managed identities in Active Directory. You can use built-in roles or custom roles for individuals and groups.

Azure Cosmos DB provides built-in Azure RBAC for common management scenarios in Azure Cosmos DB. An individual who has a profile in Azure Active Directory (AD) can assign these Azure roles to users, groups, service principals, or managed identities to grant or deny access to resources and operations on Azure Cosmos DB resources.

You can also use the Azure AD PowerShell module to perform adhoc queries to discover accounts that are members of administrative groups.

Additionally, some actions in Azure Cosmos DB can be controlled with Azure Active Directory and account-specific primary keys. Use the 'disableKeyBasedMetadataWriteAccess' account setting to control key access.

Understand Azure role-based access control in Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/role-based-access-control

Build your own custom roles using Azure Cosmos DB Actions (Microsoft.DocumentDB namespace): https://docs.microsoft.com/azure/role-based-access-control/resource-provider-operations#microsoftdocumentdb

Create a new role in Azure Active Directory: https://docs.microsoft.com/azure/role-based-access-control/custom-

roles

How to get a directory role in Azure Active Directory with PowerShell: https://docs.microsoft.com/powershell/module/azuread/get-azureaddirectoryrole?view=azureadps-2.0&preserve-view=true

How to get members of a directory role in Azure Active Directory with PowerShell: https://docs.microsoft.com/powershell/module/azuread/get-azureaddirectoryrolemember?view=azureadps-2.0&preserve-view=true

Restrict user access to data operations only: https://docs.microsoft.com/azure/cosmos-db/how-to-restrict-user-data

Azure Security Center monitoring: Yes

Responsibility: Customer

3.2: Change default passwords where applicable

Guidance: The concept of default or blank passwords does not exist in relation to Azure AD or Azure Cosmos DB. Instead, Azure Cosmos DB uses two types of keys to authenticate users and provide access to its data and resources; primary keys and resource tokens. The keys can be regenerated at any time.

Understanding secure access to data in Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/secure-access-to-data

How to regenerate Azure Cosmos DB Keys: https://docs.microsoft.com/azure/cosmos-db/manage-with-powershell#regenerate-keys

How to programmatically access keys using Azure Active Directory: https://docs.microsoft.com/azure/cosmos-db/certificate-based-authentication

Azure Security Center monitoring: Not applicable

Responsibility: Shared

3.3: Use dedicated administrative accounts

Guidance: Not applicable; Azure Cosmos DB does not support administrator accounts. All access is integrated with Azure Active Directory and Azure role-based access control (Azure RBAC).

Azure Security Center monitoring: Not applicable

Responsibility: Customer

3.4: Use single sign-on (SSO) with Azure Active Directory

Guidance: Azure Cosmos DB uses two types of keys to authorize users and does not support Single Sign-On (SSO) at the data plane level. Access to the control plane for Cosmos DB is available via REST API and supports SSO. To authenticate, set the Authorization header for your requests to a JSON Web Token that you obtain from Azure Active Directory.

Understand Azure Database for Cosmos DB REST API: https://docs.microsoft.com/rest/api/cosmos-db/

Understand SSO with Azure Active Directory: https://docs.microsoft.com/azure/active-directory/manage-apps/what-is-single-sign-on

Azure Security Center monitoring: Not applicable

Responsibility: Customer

3.5: Use multi-factor authentication for all Azure Active Directory based access

Guidance: Enable Azure Active Directory Multi-Factor Authentication and follow Azure Security Center Identity

and Access Management recommendations.

How to enable MFA in Azure: https://docs.microsoft.com/azure/active-directory/authentication/howto-mfa-getstarted

How to monitor identity and access within Azure Security Center: https://docs.microsoft.com/azure/security-center/security-center-identity-access

Azure Security Center monitoring: Yes

Responsibility: Customer

3.6: Use dedicated machines (Privileged Access Workstations) for all administrative tasks

Guidance: Use Privileged Access Workstations (PAW) with Multi-Factor Authentication configured to log into and configure Azure resources.

Learn about Privileged Access Workstations: https://docs.microsoft.com/windows-server/identity/securing-privileged-access/privileged-access-workstations

How to enable MFA in Azure: https://docs.microsoft.com/azure/active-directory/authentication/howto-mfa-getstarted

Azure Security Center monitoring: Not applicable

Responsibility: Customer

3.7: Log and alert on suspicious activity from administrative accounts

Guidance: Use Advanced Threat Protection (ATP) for Azure Cosmos DB. ATP for Azure Cosmos DB provides an additional layer of security intelligence that detects unusual and potentially harmful attempts to access or exploit Azure Cosmos accounts. This layer of protection allows you to address threats and integrate them with central security monitoring systems.

In addition, you may use Azure Active Directory (AD) Privileged Identity Management (PIM) for generation of logs and alerts when suspicious or unsafe activity occurs in the environment.

Use Azure AD Risk Detections to view alerts and reports on risky user behavior.

How to deploy Privileged Identity Management (PIM): https://docs.microsoft.com/azure/active-directory/privileged-identity-management/pim-deployment-plan

Understand Azure AD risk detections: https://docs.microsoft.com/azure/active-directory/reports-monitoring/concept-risk-events

Azure Security Center monitoring: Yes

Responsibility: Customer

3.8: Manage Azure resources from only approved locations

Guidance: Configure the location condition of a Conditional Access policy and manage your named locations. With named locations, you can create logical groupings of IP address ranges or countries and regions. You can restrict access to sensitive resources, such as your Azure Cosmos DB instances, to your configured named locations.

How to configure Named Locations in Azure: https://docs.microsoft.com/azure/active-directory/reports-monitoring/quickstart-configure-named-locations

Azure Security Center monitoring: Not applicable

Responsibility: Customer

3.9: Use Azure Active Directory

Guidance: Use Azure Active Directory (AD) as the central authentication and authorization system. Azure AD protects data by using strong encryption for data at rest and in transit. Azure AD also salts, hashes, and securely stores user credentials.

How to create and configure an Azure Active Directory instance: https://docs.microsoft.com/azure/active-directory-domain-services/tutorial-create-instance

How to configure and manage Azure Active Directory authentication with Azure SQL: https://docs.microsoft.com/azure/sql-database/sql-database-aad-authentication-configure

Azure Security Center monitoring: Not applicable

Responsibility: Customer

3.10: Regularly review and reconcile user access

Guidance: Azure Active Directory provides logs to help discover stale accounts. In addition, you can use Azure Identity Access Reviews to efficiently manage group memberships, access to enterprise applications, and role assignments. User's access can be reviewed on a regular basis to make sure only the right Users have continued access.

How to use Azure Identity Access Reviews: https://docs.microsoft.com/azure/active-directory/governance/access-reviews-overview

Azure Security Center monitoring: Yes

Responsibility: Customer

3.11: Monitor attempts to access deactivated accounts

Guidance: You can create diagnostic settings for Azure Active Directory user accounts, sending the audit logs and sign-in logs to a Log Analytics workspace where you can configure desired alerts.

How to integrate Azure Activity Logs into Azure Monitor: https://docs.microsoft.com/azure/active-directory/reports-monitoring/howto-integrate-activity-logs-with-log-analytics

Azure Security Center monitoring: Currently not available

Responsibility: Customer

3.12: Alert on account login behavior deviation

Guidance: Use Advanced Threat Protection (ATP) for Azure Cosmos DB. ATP for Azure Cosmos DB provides an additional layer of security intelligence that detects unusual and potentially harmful attempts to access or exploit Azure Cosmos accounts. This layer of protection allows you to address threats and integrate them with central security monitoring systems.

You can also use Azure AD Identity Protection and risk detections feature to configure automated responses to detected suspicious actions related to user identities. Additionally, you can ingest logs into Azure Sentinel for further investigation.

How to view Azure Active Directory risky sign-ins: https://docs.microsoft.com/azure/active-directory/reports-monitoring/concept-risky-sign-ins

How to configure and enable Identity Protection risk policies: https://docs.microsoft.com/azure/active-directory/identity-protection/howto-identity-protection-configure-risk-policies

How to onboard Azure Sentinel: https://docs.microsoft.com/azure/sentinel/quickstart-onboard

Azure Security Center monitoring: Yes

Responsibility: Customer

3.13: Provide Microsoft with access to relevant customer data during support scenarios

Guidance: Customer Lockbox is not applicable for Cosmos DB. Microsoft employees cannot access data resources even with customer permissions.

List of Customer Lockbox supported services: https://docs.microsoft.com/azure/security/fundamentals/customer-lockbox-overview#supported-services-and-scenarios-in-general-availability

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

Data Protection

For more information, see Security Control: Data Protection.

4.1: Maintain an inventory of sensitive Information

Guidance: Use tags to assist in tracking Azure Cosmos DB instances that store or process sensitive information.

How to create and use tags: https://docs.microsoft.com/azure/azure-resource-manager/resource-group-using-tags

Azure Security Center monitoring: Not applicable

Responsibility: Customer

4.2: Isolate systems storing or processing sensitive information

Guidance: Implement separate subscriptions and/or management groups for development, test, and production. Azure Cosmos DB instances are separated by virtual network/subnet, tagged appropriately, and secured within a network security group (NSG) or Azure Firewall. Azure Cosmos DB instances storing sensitive data should be isolated. By using Azure Private Link, you can connect to an Azure Cosmos DB instance account via a private endpoint. The private endpoint is a set of private IP addresses in a subnet within your virtual network. You can then limit access to the selected private IP addresses.

How to create additional Azure subscriptions: https://docs.microsoft.com/azure/billing/billing-create-subscription

How to create management groups: https://docs.microsoft.com/azure/governance/management-groups/create

How to create and use tags: https://docs.microsoft.com/azure/azure-resource-manager/resource-group-using-tags

How to configure a Private Endpoint for Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/how-to-configure-private-endpoints

How to create a Network Security Group with a Security Config: https://docs.microsoft.com/azure/virtual-network/tutorial-filter-network-traffic

Azure Security Center monitoring: Not applicable

Responsibility: Customer

4.3: Monitor and block unauthorized transfer of sensitive information

Guidance: You can deploy Advanced Threat Protection for Azure Cosmos DB, which will detect anomalous activities indicating unusual and potentially harmful attempts to access or exploit databases. It can currently trigger the following alerts:

- Access from unusual locations
- Unusual data extraction

Additionally, when using virtual machines to access your Azure Cosmos DB instances, make use of Private Link, Firewall, network security groups, and service tags to mitigate the possibility of data exfiltration. Microsoft manages the underlying infrastructure for Azure Cosmos DB and has implemented strict controls to prevent the

loss or exposure of customer data.

How to configure Cosmos DB Advanced Threat Protection: https://docs.microsoft.com/azure/cosmos-db/cosmos-db-advanced-threat-protection

Understand customer data protection in Azure: https://docs.microsoft.com/azure/security/fundamentals/protection-customer-data

Azure Security Center monitoring: Yes

Responsibility: Shared

4.4: Encrypt all sensitive information in transit

Guidance: All connections to Azure Cosmos DB support HTTPS. Azure Cosmos DB also supports TLS1.2. It is possible to enforce a minimum TLS version server-side. To do so, please contact azurecosmosdbtls@service.microsoft.com.

Overview of Cosmos DB Security: https://docs.microsoft.com/azure/cosmos-db/database-security

Azure Security Center monitoring: Not applicable

Responsibility: Microsoft

4.5: Use an active discovery tool to identify sensitive data

Guidance: Automatic data identification, classification, and loss prevention features are not yet available for Azure Cosmos DB. However, you can use the Azure Cognitive Search integration for classification and data analysis. You can also implement a third-party solution if required for compliance purposes.

For the underlying platform which is managed by Microsoft, Microsoft treats all customer content as sensitive and goes to great lengths to guard against customer data loss and exposure. To ensure customer data within Azure remains secure, Microsoft has implemented and maintains a suite of robust data protection controls and capabilities.

Index Azure Cosmos DB data with Azure Cognitive Search: https://docs.microsoft.com/azure/search/search-howto-index-cosmosdb?toc=/azure/cosmos-db/toc.json&bc=/azure/cosmos-db/breadcrumb/toc.json

Understand customer data protection in Azure: https://docs.microsoft.com/azure/security/fundamentals/protection-customer-data

Azure Security Center monitoring: Currently not available

Responsibility: Shared

4.6: Use Azure RBAC to control access to resources

Guidance: Azure Cosmos DB provides built-in Azure role-based access control (Azure RBAC) for common management scenarios in Azure Cosmos DB. An individual who has a profile in Azure Active Directory can assign these Azure roles to users, groups, service principals, or managed identities to grant or deny access to resources and operations on Azure Cosmos DB resources. Role assignments are scoped to control-plane access only, which includes access to Azure Cosmos accounts, databases, containers, and offers (throughput).

How to implement Azure RBAC in Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/role-based-access-control

Azure Security Center monitoring: Not applicable

Responsibility: Customer

4.7: Use host-based data loss prevention to enforce access control

Guidance: Not applicable; this guideline is intended for compute resources.

Microsoft manages the underlying infrastructure for Cosmos DB and has implemented strict controls to prevent the loss or exposure of customer data.

Understand customer data protection in Azure: https://docs.microsoft.com/azure/security/fundamentals/protection-customer-data

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

4.8: Encrypt sensitive information at rest

Guidance: All user data stored in Cosmos DB is encrypted at rest by default. There are no controls to turn it off. Azure Cosmos DB uses AES-256 encryption on all regions where the account is running.

By default, Microsoft manages the keys that are used to encrypt the data in your Azure Cosmos account. You can optionally choose to add a second layer of encryption with your own keys.

Understanding encryption at rest with Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/database-encryption-at-rest

Understanding key management for encryption at rest with Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/cosmos-db-security-controls

How to configure customer-managed keys for your Azure Cosmos DB account: https://docs.microsoft.com/azure/cosmos-db/how-to-setup-cmk

Azure Security Center monitoring: Not applicable

Responsibility: Shared

4.9: Log and alert on changes to critical Azure resources

Guidance: Use Azure Monitor with the Azure Activity Log to create alerts for when changes take place to production instances of Azure Cosmos DB.

How to create alerts for Azure Activity Log events: https://docs.microsoft.com/azure/azure-monitor/platform/alerts-activity-log

How to create alerts for Azure Activity Log events: https://docs.microsoft.com/azure/azure-monitor/platform/alerts-activity-log

Azure Security Center monitoring: Not applicable

Responsibility: Customer

Vulnerability Management

For more information, see Security Control: Vulnerability Management.

5.1: Run automated vulnerability scanning tools

Guidance: Follow recommendations from Azure Security Center for your Azure Cosmos DB instances.

Microsoft performs system patching and vulnerability management on the underlying hosts that support your Azure Cosmos DB instances. To ensure customer data within Azure remains secure, Microsoft has implemented and maintains a suite of robust data protection controls and capabilities.

Supported features available in Azure Security Center: https://docs.microsoft.com/azure/security-center/security-center-services?tabs=features-windows

Azure Security Center monitoring: Yes

Responsibility: Shared

5.2: Deploy automated operating system patch management solution

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

5.3: Deploy automated third-party software patch management solution

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

5.4: Compare back-to-back vulnerability scans

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

5.5: Use a risk-rating process to prioritize the remediation of discovered vulnerabilities

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

Inventory and Asset Management

For more information, see Security Control: Inventory and Asset Management.

6.1: Use Azure Asset Discovery

Guidance: Use the Azure portal or Azure Resource Graph to discover all resources (not limited to Azure Cosmos DB, but also including resources such as compute, other storage, network, ports, and protocols etc.) within your subscription(s). Ensure you have appropriate permissions in your tenant and are able to enumerate all Azure subscriptions as well as resources within your subscriptions.

Although classic Azure resources may be discovered via Resource Graph, it is highly recommended to create and use Azure Resource Manager resources going forward.

How to create queries with Azure Resource Graph: https://docs.microsoft.com/azure/governance/resource-graph/first-query-portal

How to view your Azure Subscriptions: https://docs.microsoft.com/powershell/module/az.accounts/get-azsubscription?view=azps-3.0.0&preserve-view=true

Understanding Azure role-based access control: https://docs.microsoft.com/azure/role-based-access-control/overview

Azure Security Center monitoring: Not applicable

Responsibility: Customer

6.2: Maintain asset metadata

Guidance: Apply tags to your Azure Cosmos DB instances and related resources with metadata to logically organize them into a taxonomy.

How to create and use tags: https://docs.microsoft.com/azure/azure-resource-manager/resource-group-using-tags

Which Azure Cosmos DB resources support tags: https://docs.microsoft.com/azure/azure-resource-manager/management/tag-support#microsoftdocumentdb

Azure Security Center monitoring: Not applicable

Responsibility: Customer

6.3: Delete unauthorized Azure resources

Guidance: Use tagging, management groups, and separate subscriptions, where appropriate, to organize and track assets, including but not limited to Azure Cosmos DB resources. Reconcile inventory on a regular basis and ensure unauthorized resources are deleted from the subscription in a timely manner.

How to create additional Azure subscriptions: https://docs.microsoft.com/azure/billing/billing-create-subscription

How to create Management Groups: https://docs.microsoft.com/azure/governance/management-groups/create

How to create and use Tags: https://docs.microsoft.com/azure/azure-resource-manager/resource-group-using-tags

Azure Security Center monitoring: Not applicable

Responsibility: Customer

6.4: Maintain an inventory of approved Azure resources and software titles

Guidance: Not applicable; this guideline is intended for compute resources and Azure as a whole.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

6.5: Monitor for unapproved Azure resources

Guidance: Use Azure Policy to put restrictions on the type of resources that can be created in customer subscription(s) using the following built-in policy definitions:

- Not allowed resource types
- Allowed resource types

In addition, use the Azure Resource Graph to query/discover resources within the subscription(s).

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

How to create queries with Azure Graph: https://docs.microsoft.com/azure/governance/resource-graph/first-query-portal

Azure Security Center monitoring: Not applicable

Responsibility: Customer

6.6: Monitor for unapproved software applications within compute resources

Guidance: Not applicable; this baseline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

6.7: Remove unapproved Azure resources and software applications

Guidance: Not applicable; this guideline is intended for compute resources and Azure as a whole.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

6.8: Use only approved applications

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

6.9: Use only approved Azure services

Guidance: Use Azure Policy to put restrictions on the type of resources that can be created in customer subscription(s) using the following built-in policy definitions:

- Not allowed resource types
- Allowed resource types

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

How to deny a specific resource type with Azure Policy: https://docs.microsoft.com/azure/governance/policy/samples/not-allowed-resource-types

Azure Security Center monitoring: Not applicable

Responsibility: Customer

6.10: Implement approved application list

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

6.11: Limit users' ability to interact with AzureResources Manager via scripts

Guidance: Use the Azure Conditional Access to limit users' ability to interact with Azure Resource Manager by configuring "Block access" for the "Microsoft Azure Management" App. This can prevent the creation and changes to resources within a high security environment.

How to configure Conditional Access to block access to Azure Resource Manager: https://docs.microsoft.com/azure/role-based-access-control/conditional-access-azure-management

Azure Security Center monitoring: Not applicable

Responsibility: Customer

6.12: Limit users' ability to execute scripts within compute resources

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

6.13: Physically or logically segregate high risk applications

Guidance: Not applicable; this guideline is intended for web applications running on Azure App Service or compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

Secure Configuration

For more information, see Security Control: Secure Configuration.

7.1: Establish secure configurations for all Azure resources

Guidance: Define and implement standard security configurations for your Cosmos DB instances with Azure Policy. Use Azure Policy aliases in the "Microsoft.DocumentDB" namespace to create custom policies to audit or enforce the configuration of your Cosmos DB instances. You may also make use of built-in policy definitions for Azure Cosmos DB, such as:

- Deploy Advanced Threat Protection for Cosmos DB Accounts
- Cosmos DB should use a virtual network service endpoint

How to view available Azure Policy aliases: https://docs.microsoft.com/powershell/module/az.resources/get-azpolicyalias?view=azps-3.3.0&preserve-view=true

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

Azure Security Center monitoring: Not applicable

Responsibility: Customer

7.2: Establish secure operating system configurations

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

7.3: Maintain secure Azure resource configurations

Guidance: Use Azure Policy [deny] and [deploy if not exist] to enforce secure settings across your Azure resources.

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

Understand Azure Policy Effects: https://docs.microsoft.com/azure/governance/policy/concepts/effects

Azure Security Center monitoring: Not applicable

Responsibility: Customer

7.4: Maintain secure operating system configurations

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

7.5: Securely store configuration of Azure resources

Guidance: If using custom Azure Policy definitions for your Cosmos DB or related resources, use Azure Repos to securely store and manage your code.

Azure Repos Documentation: https://docs.microsoft.com/azure/devops/repos/index?view=azure-devops&preserve-view=true https://docs.microsoft.com/azure/devops/repos/git/gitworkflow?view=azure-devops&preserve-view=true

Azure Security Center monitoring: Not applicable

Responsibility: Customer

7.6: Securely store custom operating system images

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

7.7: Deploy system configuration management tools

Guidance: Use Azure Policy aliases in the "Microsoft.DocumentDB" namespace to create custom policies to alert, audit, and enforce system configurations. Additionally, develop a process and pipeline for managing policy exceptions.

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

Azure Security Center monitoring: Not applicable

Responsibility: Customer

7.8: Deploy system configuration management tools for operating systems

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

7.9: Implement automated configuration monitoring for Azure services

Guidance: Use Azure Policy aliases in the "Microsoft.DocumentDB" namespace to create custom policies to alert, audit, and enforce system configurations. Use Azure Policy [audit], [deny], and [deploy if not exist] to automatically enforce configurations for your Azure Cosmos DB instances and related resources.

How to configure and manage Azure Policy: https://docs.microsoft.com/azure/governance/policy/tutorials/create-and-manage

Azure Security Center monitoring: Not applicable

Responsibility: Customer

7.10: Implement automated configuration monitoring for operating systems

Guidance: Not applicable; this guideline is intended for compute resources.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

7.11: Manage Azure secrets securely

Guidance: For Azure virtual machines or web applications running on Azure App Service being used to access your Azure Cosmos DB instances, use Managed Service Identity in conjunction with Azure Key Vault to simplify and secure Azure Cosmos DB secret management. Ensure Key Vault Soft Delete is enabled.

How to integrate with Azure Managed Identities: https://docs.microsoft.com/azure/azure-app-configuration/howto-integrate-azure-managed-service-identity

How to create a Key Vault: https://docs.microsoft.com/azure/key-vault/general/quick-create-portal

How to authenticate to Key Vault: https://docs.microsoft.com/azure/key-vault/general/authentication

How to assign a Key Vault access policy: https://docs.microsoft.com/azure/key-vault/general/assign-access-policy-portal

Azure Security Center monitoring: Yes

Responsibility: Customer

7.12: Manage identities securely and automatically

Guidance: For Azure virtual machines or web applications running on Azure App Service being used to access your Azure Cosmos DB instances, use Managed Service Identity in conjunction with Azure Key Vault to simplify and secure Azure Cosmos DB secret management.

Use Managed Identities to provide Azure services with an automatically managed identity in Azure Active Directory (AD). Managed Identities allows you to authenticate to any service that supports Azure AD authentication, including Key Vault, without any credentials in your code.

How to configure Managed Identities: https://docs.microsoft.com/azure/active-directory/managed-identities-azure-resources/qs-configure-portal-windows-vm

How to integrate with Azure Managed Identities: https://docs.microsoft.com/azure/azure-app-configuration/howto-integrate-azure-managed-service-identity

Azure Security Center monitoring: Yes

Responsibility: Customer

7.13: Eliminate unintended credential exposure

Guidance: Implement Credential Scanner to identify credentials within code. Credential Scanner will also encourage moving discovered credentials to more secure locations such as Azure Key Vault.

How to set up Credential Scanner: https://secdevtools.azurewebsites.net/helpcredscan.html

Azure Security Center monitoring: Not applicable

Responsibility: Customer

Malware Defense

For more information, see Security Control: Malware Defense.

8.1: Use centrally managed anti-malware software

Guidance: Not applicable; this guideline is intended for compute resources. Microsoft Antimalware is enabled on the underlying host that supports Azure services (for example, Azure App Service), however it does not run on customer content.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

8.2: Pre-scan files to be uploaded to non-compute Azure resources

Guidance: Microsoft Antimalware is enabled on the underlying host that supports Azure services (for example, Azure App Service), however it does not run on customer content.

It is your responsibility to pre-scan any files being uploaded to non-compute Azure resources, including Azure Cosmos DB. Microsoft cannot access customer data, and therefore cannot conduct anti-malware scans of customer content on your behalf.

Azure Security Center monitoring: Not applicable

Responsibility: Customer

8.3: Ensure anti-malware software and signatures are updated

Guidance: Not applicable; benchmark is intended for compute resources. Microsoft Antimalware is enabled on the underlying host that supports Azure services, however it does not run on customer content.

Azure Security Center monitoring: Not applicable

Responsibility: Not applicable

Data Recovery

For more information, see Security Control: Data Recovery.

9.1: Ensure regular automated back ups

Guidance: Azure Cosmos DB takes snapshots of your data every four hours. All the backups are stored separately in a storage service, and those backups are globally replicated for resiliency against regional disasters. At any given time, only the last two snapshots are retained. However, if the container or database is deleted, Azure Cosmos DB retains the existing snapshots of a given container or database for 30 days. Contact Azure Support to restore from a backup.

Understanding Azure Cosmos DB Automated Backups: https://docs.microsoft.com/azure/cosmos-db/online-backup-and-restore

Azure Security Center monitoring: Not applicable

Responsibility: Microsoft

9.2: Perform complete system backups and backup any customer managed keys

Guidance: Azure Cosmos DB automatically takes backups of your data at regular intervals. If database or container is deleted, you can file a support ticket or call Azure support to restore the data from automatic online backups. Azure support is available for selected plans only such as Standard, Developer, and plans higher than them. To restore a specific snapshot of the backup, Azure Cosmos DB requires that the data is available for the duration of the backup cycle for that snapshot.

If using Key Vault to store credentials for your Cosmos DB instances, ensure regular automated backups of your keys.

Understand Azure Cosmos DB Automated Backups: https://docs.microsoft.com/azure/cosmos-db/online-backup-and-restore

How to restore data in Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/how-to-backup-and-restore

How to backup Key Vault Keys: https://docs.microsoft.com/powershell/module/azurerm.keyvault/backup-azurekeyvaultkey

Azure Security Center monitoring: Currently not available

Responsibility: Shared

9.3: Validate all backups including customer managed keys

Guidance: If database or container is deleted, you can file a support ticket or call Azure support to restore the data from automatic online backups. Azure support is available for selected plans only such as Standard, Developer, and plans higher than them. To restore a specific snapshot of the backup, Azure Cosmos DB requires that the data is available for the duration of the backup cycle for that snapshot.

Test restoration of your secrets stored in Azure Key Vault using PowerShell. The Restore-AzureKeyVaultKey cmdlet creates a key in the specified key vault. This key is a replica of the backed-up key in the input file and has the same name as the original key.

Understand Azure Cosmos DB Automated Backups:

https://docs.microsoft.com/azure/cosmos-db/online-backup-and-restore

How to restore data in Azure Cosmos DB:

https://docs.microsoft.com/azure/cosmos-db/how-to-backup-and-restore

How to restore Azure Key Vault Secrets:

https://docs.microsoft.com/powershell/module/azurerm.keyvault/restore-azurekeyvaultkey?view=azurermps-6.13.0&preserve-view=true

Azure Security Center monitoring: Not applicable

Responsibility: Shared

9.4: Ensure protection of backups and customer managed keys

Guidance: Because all user data stored in Cosmos DB is encrypted at rest and in transport, you don't have to take any action. Another way to put this is that encryption at rest is "on" by default. There are no controls to turn it off or on. Azure Cosmos DB uses AES-256 encryption on all regions where the account is running.

Enable Soft-Delete in Key Vault to protect keys against accidental or malicious deletion.

Understand data encryption in Azure Cosmos DB: https://docs.microsoft.com/azure/cosmos-db/database-encryption-at-rest

How to enable Soft-Delete in Key Vault: https://docs.microsoft.com/azure/storage/blobs/storage-blob-soft-delete?tabs=azure-portal

Azure Security Center monitoring: Yes

Responsibility: Shared

Incident Response

For more information, see Security Control: Incident Response.

10.1: Create an incident response guide

Guidance: Build out an incident response guide for your organization. Ensure that there are written incident response plans that define all roles of personnel as well as phases of incident handling/management from detection to post-incident review.

You may also leverage NIST's Computer Security Incident Handling Guide to aid in the creation of your own incident response plan: https://nvlpubs.nist.gov/nistpubs/SpecialPublications/NIST.SP.800-61r2.pdf

How to configure Workflow Automations within Azure Security Center: https://docs.microsoft.com/azure/security-center/security-center-planning-and-operations-guide

Guidance on building your own security incident response process: https://msrc-blog.microsoft.com/2019/07/01/inside-the-msrc-building-your-own-security-incident-response-process/

Microsoft Security Response Center's Anatomy of an Incident: https://msrc-blog.microsoft.com/2019/07/01/inside-the-msrc-building-your-own-security-incident-response-process/

Azure Security Center monitoring: Not applicable

Responsibility: Customer

10.2: Create an incident scoring and prioritization procedure

Guidance: Security Center assigns a severity to each alert to help you prioritize which alerts should be investigated first. The severity is based on how confident the Security Center is in finding or the analytics used to

issue the alert as well as the confidence level that there was malicious intent behind the activity that led to the alert.

Additionally, clearly mark subscriptions (for ex. production, non-prod) and create a naming system to clearly identify and categorize Azure resources.

Azure Security Center monitoring: Not applicable

Responsibility: Customer

10.3: Test security response procedures

Guidance: Conduct exercises to test your systems' incident response capabilities on a regular cadence. Identify weak points and gaps and revise plan as needed.

Refer to NIST's publication: Guide to Test, Training, and Exercise Programs for IT Plans and Capabilities: https://nvlpubs.nist.gov/nistpubs/Legacy/SP/nistspecialpublication800-84.pdf

Azure Security Center monitoring: Not applicable

Responsibility: Customer

10.4: Provide security incident contact details and configure alert notifications for security incidents

Guidance: Security incident contact information will be used by Microsoft to contact you if the Microsoft Security Response Center (MSRC) discovers that the customer's data has been accessed by an unlawful or unauthorized party. Review incidents after the fact to ensure that issues are resolved.

How to set the Azure Security Center Security Contact: https://docs.microsoft.com/azure/security-center/security-center-provide-security-contact-details

Azure Security Center monitoring: Yes

Responsibility: Customer

10.5: Incorporate security alerts into your incident response system

Guidance: Export your Azure Security Center alerts and recommendations using the Continuous Export feature. Continuous Export allows you to export alerts and recommendations either manually or in an ongoing, continuous fashion. You may use the Azure Security Center data connector to stream the alerts Sentinel.

How to configure continuous export: https://docs.microsoft.com/azure/security-center/continuous-export

How to stream alerts into Azure Sentinel: https://docs.microsoft.com/azure/sentinel/connect-azure-security-center

Azure Security Center monitoring: Not applicable

Responsibility: Customer

10.6: Automate the response to security alerts

Guidance: Use the Workflow Automation feature in Azure Security Center to automatically trigger responses via "Logic Apps" on security alerts and recommendations.

How to configure Workflow Automation and Logic Apps: https://docs.microsoft.com/azure/security-center/workflow-automation

Azure Security Center monitoring: Not applicable

Responsibility: Customer

Penetration Tests and Red Team Exercises

For more information, see Security Control: Penetration Tests and Red Team Exercises.

11.1: Conduct regular penetration testing of your Azure resources and ensure remediation of all critical security

findings within 60 days

Guidance: Follow the Microsoft Rules of Engagement to ensure your Penetration Tests are not in violation of Microsoft policies: https://www.microsoft.com/msrc/pentest-rules-of-engagement?rtc=1

You can find more information on Microsoft's strategy and execution of Red Teaming and live site penetration testing against Microsoft-managed cloud infrastructure, services, and applications, here: https://gallery.technet.microsoft.com/Cloud-Red-Teaming-b837392e

Azure Security Center monitoring: Not applicable

Responsibility: Shared

What is Azure Synapse Link for Azure Cosmos DB?

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API Azure Cosmos DB API for MongoDB

> **IMPORTANT**
>
> Synapse serverless SQL pool support for Azure Synapse Link for Azure Cosmos DB is currently in preview. This preview version is provided without a service level agreement, and it's not recommended for production workloads. For more information, see Supplemental terms of use for Microsoft Azure previews.

Azure Synapse Link for Azure Cosmos DB is a cloud-native hybrid transactional and analytical processing (HTAP) capability that enables you to run near real-time analytics over operational data in Azure Cosmos DB. Azure Synapse Link creates a tight seamless integration between Azure Cosmos DB and Azure Synapse Analytics.

Using Azure Cosmos DB analytical store, a fully isolated column store, Azure Synapse Link enables no Extract-Transform-Load (ETL) analytics in Azure Synapse Analytics against your operational data at scale. Business analysts, data engineers and data scientists can now use Synapse Spark or Synapse SQL interchangeably to run near real-time business intelligence, analytics, and machine learning pipelines. You can achieve this without impacting the performance of your transactional workloads on Azure Cosmos DB.

The following image shows the Azure Synapse Link integration with Azure Cosmos DB and Azure Synapse Analytics:

Benefits

To analyze large operational datasets while minimizing the impact on the performance of mission-critical transactional workloads, traditionally, the operational data in Azure Cosmos DB is extracted and processed by Extract-Transform-Load (ETL) pipelines. ETL pipelines require many layers of data movement resulting in much operational complexity, and performance impact on your transactional workloads. It also increases the latency to analyze the operational data from the time of origin.

When compared to the traditional ETL-based solutions, Azure Synapse Link for Azure Cosmos DB offers several advantages such as:

Reduced complexity with No ETL jobs to manage

Azure Synapse Link allows you to directly access Azure Cosmos DB analytical store using Azure Synapse Analytics without complex data movement. Any updates made to the operational data are visible in the analytical store in near real-time with no ETL or change feed jobs. You can run large scale analytics against analytical store, from Azure Synapse Analytics, without additional data transformation.

Near real-time insights into your operational data

You can now get rich insights on your operational data in near real-time, using Azure Synapse Link. ETL-based systems tend to have higher latency for analyzing your operational data, due to many layers needed to extract, transform and load the operational data. With native integration of Azure Cosmos DB analytical store with Azure Synapse Analytics, you can analyze operational data in near real-time enabling new business scenarios.

No impact on operational workloads

With Azure Synapse Link, you can run analytical queries against an Azure Cosmos DB analytical store (a separate column store) while the transactional operations are processed using provisioned throughput for the transactional workload (a row-based transactional store). The analytical workload is served independent of the transactional workload traffic without consuming any of the throughput provisioned for your operational data.

Optimized for large-scale analytics workloads

Azure Cosmos DB analytical store is optimized to provide scalability, elasticity, and performance for analytical workloads without any dependency on the compute run-times. The storage technology is self-managed to optimize your analytics workloads. With built-in support into Azure Synapse Analytics, accessing this storage layer provides simplicity and high performance.

Cost effective

With Azure Synapse Link, you can get a cost-optimized, fully managed solution for operational analytics. It eliminates the extra layers of storage and compute required in traditional ETL pipelines for analyzing operational data.

Azure Cosmos DB analytical store follows a consumption-based pricing model, which is based on data storage and analytical read/write operations and queries executed . It doesn't require you to provision any throughput, as you do today for the transactional workloads. Accessing your data with highly elastic compute engines from Azure Synapse Analytics makes the overall cost of running storage and compute very efficient.

Analytics for locally available, globally distributed, multi-region writes

You can run analytical queries effectively against the nearest regional copy of the data in Azure Cosmos DB. Azure Cosmos DB provides the state-of-the-art capability to run the globally distributed analytical workloads along with transactional workloads in an active-active manner.

Enable HTAP scenarios for your operational data

Synapse Link brings together Azure Cosmos DB analytical store with Azure Synapse analytics runtime support. This integration enables you to build cloud native HTAP (Hybrid transactional/analytical processing) solutions that generate insights based on real-time updates to your operational data over large datasets. It unlocks new business scenarios to raise alerts based on live trends, build near real-time dashboards, and business experiences based on user behavior.

Azure Cosmos DB analytical store

Azure Cosmos DB analytical store is a column-oriented representation of your operational data in Azure Cosmos DB. This analytical store is suitable for fast, cost effective queries on large operational data sets, without copying data and impacting the performance of your transactional workloads.

Analytical store automatically picks up high frequency inserts, updates, deletes in your transactional workloads in near real time, as a fully managed capability ("auto-sync") of Azure Cosmos DB. No change feed or ETL is

required.

If you have a globally distributed Azure Cosmos DB account, after you enable analytical store for a container, it will be available in all regions for that account. For more information on the analytical store, see Azure Cosmos DB Analytical store overview article.

Integration with Azure Synapse Analytics

With Synapse Link, you can now directly connect to your Azure Cosmos DB containers from Azure Synapse Analytics and access the analytical store with no separate connectors. Azure Synapse Analytics currently supports Synapse Link with Synapse Apache Spark and serverless SQL pool.

You can query the data from Azure Cosmos DB analytical store simultaneously, with interop across different analytics run times supported by Azure Synapse Analytics. No additional data transformations are required to analyze the operational data. You can query and analyze the analytical store data using:

- Synapse Apache Spark with full support for Scala, Python, SparkSQL, and C#. Synapse Spark is central to data engineering and data science scenarios
- Serverless SQL pool with T-SQL language and support for familiar BI tools (for example, Power BI Premium, etc.)

> **NOTE**
> From Azure Synapse Analytics, you can access both analytical and transactional stores in your Azure Cosmos DB container. However, if you want to run large-scale analytics or scans on your operational data, we recommend that you use analytical store to avoid performance impact on transactional workloads.

> **NOTE**
> You can run analytics with low latency in an Azure region by connecting your Azure Cosmos DB container to Synapse runtime in that region.

This integration enables the following HTAP scenarios for different users:

- A BI engineer who wants to model and publish a Power BI report to access the live operational data in Azure Cosmos DB directly through Synapse SQL.
- A data analyst who wants to derive insights from the operational data in an Azure Cosmos DB container by querying it with Synapse SQL, read the data at scale and combine those findings with other data sources.
- A data scientist who wants to use Synapse Spark to find a feature to improve their model and train that model without doing complex data engineering. They can also write the results of the model post inference into Azure Cosmos DB for real-time scoring on the data through Spark Synapse.
- A data engineer who wants to make data accessible for consumers, by creating SQL or Spark tables over Azure Cosmos DB containers without manual ETL processes.

For more information on Azure Synapse Analytics runtime support for Azure Cosmos DB, see Azure Synapse Analytics for Cosmos DB support.

When to use Azure Synapse Link for Azure Cosmos DB?

Synapse Link is recommended in the following cases:

- If you are an Azure Cosmos DB customer and you want to run analytics, BI, and machine learning over your operational data. In such cases, Synapse Link provides a more integrated analytics experience without

impacting your transactional store's provisioned throughput. For example:

  - If you are running analytics or BI on your Azure Cosmos DB operational data directly using separate connectors today, or
  - If you are running ETL processes to extract operational data into a separate analytics system.

In such cases, Synapse Link provides a more integrated analytics experience without impacting your transactional store's provisioned throughput.

Synapse Link is not recommended if you are looking for traditional data warehouse requirements such as high concurrency, workload management, and persistence of aggregates across multiple data sources. For more information, see common scenarios that can be powered with Azure Synapse Link for Azure Cosmos DB.

Limitations

- Today Azure Synapse Link for Azure Cosmos DB is supported for SQL API and Azure Cosmos DB API for MongoDB. It is not supported for Gremlin API and Table API. Support for Cassandra API is in private preview, for more information please contact the Azure Synapse Link team.
- Currently, the analytical store can only be enabled for new containers. To use analytical store for existing containers, migrate data from your existing containers to new containers using Azure Cosmos DB migration tools. You can enable Synapse Link on new and existing Azure Cosmos DB accounts.
- For the containers with analytical store turned on, automatic backup and restore of your data in the analytical store is not supported at this time. When Synapse Link is enabled on a database account, Azure Cosmos DB will continue to automatically take backups of your data in the transactional store (only) of containers at scheduled backup interval, as always. It is important to note that when a container with analytical store turned on is restored to a new account, the container will be restored with only transactional store and no analytical store enabled.
- Accessing the Azure Cosmos DB analytics store with Synapse SQL provisioned is currently not available.

Pricing

The billing model of Azure Synapse Link includes the costs incurred by using the Azure Cosmos DB analytical store and the Synapse runtime. To learn more, see the Azure Cosmos DB analytical store pricing and Azure Synapse Analytics pricing articles.

What is Azure Cosmos DB analytical store?

12/4/2020 • 14 minutes to read • Edit Online

APPLIES TO: SQL API Azure Cosmos DB API for MongoDB

Azure Cosmos DB analytical store is a fully isolated column store for enabling large-scale analytics against operational data in your Azure Cosmos DB, without any impact to your transactional workloads.

Azure Cosmos DB transactional store is schema-agnostic, and it allows you to iterate on your transactional applications without having to deal with schema or index management. In contrast to this, Azure Cosmos DB analytical store is schematized to optimize for analytical query performance. This article describes in detailed about analytical storage.

Challenges with large-scale analytics on operational data

The multi-model operational data in an Azure Cosmos DB container is internally stored in an indexed row-based "transactional store". Row store format is designed to allow fast transactional reads and writes in the order-of-milliseconds response times, and operational queries. If your dataset grows large, complex analytical queries can be expensive in terms of provisioned throughput on the data stored in this format. High consumption of provisioned throughput in turn, impacts the performance of transactional workloads that are used by your real-time applications and services.

Traditionally, to analyze large amounts of data, operational data is extracted from Azure Cosmos DB's transactional store and stored in a separate data layer. For example, the data is stored in a data warehouse or data lake in a suitable format. This data is later used for large-scale analytics and analyzed using compute engine such as the Apache Spark clusters. This separation of analytical storage and compute layers from operational data results in additional latency, because the ETL(Extract, Transform, Load) pipelines are run less frequently to minimize the potential impact on your transactional workloads.

The ETL pipelines also become complex when handling updates to the operational data when compared to handling only newly ingested operational data.

Column-oriented analytical store

Azure Cosmos DB analytical store addresses the complexity and latency challenges that occur with the traditional ETL pipelines. Azure Cosmos DB analytical store can automatically sync your operational data into a separate column store. Column store format is suitable for large-scale analytical queries to be performed in an optimized manner, resulting in improving the latency of such queries.

Using Azure Synapse Link, you can now build no-ETL HTAP solutions by directly linking to Azure Cosmos DB analytical store from Azure Synapse Analytics. It enables you to run near real-time large-scale analytics on your operational data.

Features of analytical store

When you enable analytical store on an Azure Cosmos DB container, a new column-store is internally created based on the operational data in your container. This column store is persisted separately from the row-oriented transactional store for that container. The inserts, updates, and deletes to your operational data are automatically synced to analytical store. You don't need the change feed or ETL to sync the data.

Column store for analytical workloads on operational data

Analytical workloads typically involve aggregations and sequential scans of selected fields. By storing the data in a column-major order, the analytical store allows a group of values for each field to be serialized together. This format reduces the IOPS required to scan or compute statistics over specific fields. It dramatically improves the query response times for scans over large data sets.

For example, if your operational tables are in the following format:

ID	Product Name	Product Code	Product Category
1	Product1	123	Books
2	Product2	250	Equipment
3	Product3	380	Equipment

The row store persists the above data in a serialized format, per row, on the disk. This format allows for faster transactional reads, writes, and operational queries, such as, "Return information about Product1". However, as the dataset grows large and if you want to run complex analytical queries on the data it can be expensive. For example, if you want to get "the sales trends for a product under the category named 'Equipment' across different business units and months", you need to run a complex query. Large scans on this dataset can get expensive in terms of provisioned throughput and can also impact the performance of the transactional workloads powering your real-time applications and services.

Analytical store, which is a column store, is better suited for such queries because it serializes similar fields of data together and reduces the disk IOPS.

The following image shows transactional row store vs. analytical column store in Azure Cosmos DB:

Decoupled performance for analytical workloads

There is no impact on the performance of your transactional workloads due to analytical queries, as the analytical store is separate from the transactional store. Analytical store does not need separate request units (RUs) to be allocated.

Auto-Sync

Auto-Sync refers to the fully managed capability of Azure Cosmos DB where the inserts, updates, deletes to operational data are automatically synced from transactional store to analytical store in near real time. Auto-sync latency is usually within 2 minutes. In cases of shared throughput database with a large number of containers, auto-sync latency of individual containers could be higher and take up to 5 minutes. We would like to learn more

how this latency fits your scenarios. For that, please reach out to the Azure Cosmos DB team.

The auto-sync capability along with analytical store provides the following key benefits:

Scalability & elasticity

By using horizontal partitioning, Azure Cosmos DB transactional store can elastically scale the storage and throughput without any downtime. Horizontal partitioning in the transactional store provides scalability & elasticity in auto-sync to ensure data is synced to the analytical store in near real time. The data sync happens regardless of the transactional traffic throughput, whether it is 1000 operations/sec or 1 million operations/sec, and it doesn't impact the provisioned throughput in the transactional store.

Automatically handle schema updates

Azure Cosmos DB transactional store is schema-agnostic, and it allows you to iterate on your transactional applications without having to deal with schema or index management. In contrast to this, Azure Cosmos DB analytical store is schematized to optimize for analytical query performance. With the auto-sync capability, Azure Cosmos DB manages the schema inference over the latest updates from the transactional store. It also manages the schema representation in the analytical store out-of-the-box which, includes handling nested data types.

As your schema evolves, and new properties are added over time, the analytical store automatically presents a unionized schema across all historical schemas in the transactional store.

Schema constraints

The following constraints are applicable on the operational data in Azure Cosmos DB when you enable analytical store to automatically infer and represent the schema correctly:

- You can have a maximum of 200 properties at any nesting level in the schema and a maximum nesting depth of 5.
  - An item with 201 properties at the top level doesn’t satisfy this constraint and hence it will not be represented in the analytical store.
  - An item with more than five nested levels in the schema also doesn’t satisfy this constraint and hence it will not be represented in the analytical store. For example, the following item doesn't satisfy the requirement:

    ```
    {"level1": {"level2":{"level3":{"level4":{"level5":{"too many":12}}}}}}
    ```

- Property names should be unique when compared case insensitively. For example, the following items do not satisfy this constraint and hence will not be represented in the analytical store:

  `{"Name": "fred"} {"name": "john"}` – "Name" and "name" are the same when compared in a case insensitive manner.

Schema representation

There are two modes of schema representation in the analytical store. These modes have tradeoffs between the simplicity of a columnar representation, handling the polymorphic schemas, and simplicity of query experience:

- Well-defined schema representation
- Full fidelity schema representation

> **NOTE**
>
> For SQL (Core) API accounts, when analytical store is enabled, the default schema representation in the analytical store is well-defined. Whereas for Azure Cosmos DB API for MongoDB accounts, the default schema representation in the analytical store is a full fidelity schema representation. If you have scenarios requiring a different schema representation than the default offering for each of these APIs, reach out to the Azure Cosmos DB team to enable it.

Well-defined schema representation

The well-defined schema representation creates a simple tabular representation of the schema-agnostic data in the transactional store. The well-defined schema representation has the following considerations:

- A property always has the same type across multiple items.
  - For example, `{"a":123} {"a": "str"}` does not have a well-defined schema because `"a"` is sometimes a string and sometimes a number. In this case, the analytical store registers the data type of `“a”` as the data type of `“a”` in the first-occurring item in the lifetime of the container. Items where the data type of `“a”` differs will not be included in the analytical store.

    This condition does not apply for null properties. For example, `{"a":123} {"a":null}` is still well defined.
- Array types must contain a single repeated type.
  - For example, `{"a": ["str",12]}` is not a well-defined schema because the array contains a mix of integer and string types.

> **NOTE**
> If the Azure Cosmos DB analytical store follows the well-defined schema representation and the specification above is violated by certain items, those items will not be included in the analytical store.

Full fidelity schema representation

The full fidelity schema representation is designed to handle the full breadth of polymorphic schemas in the schema-agnostic operational data. In this schema representation, no items are dropped from the analytical store even if the well-defined schema constraints (that is no mixed data type fields nor mixed data type arrays) are violated.

This is achieved by translating the leaf properties of the operational data into the analytical store with distinct columns based on the data type of values in the property. The leaf property names are extended with data types as a suffix in the analytical store schema such that they can be queries without ambiguity.

For example, let’s take the following sample document in the transactional store:

```
{
name: "John Doe",
age: 32,
profession: "Doctor",
address: {
  streetNo: 15850,
  streetName: "NE 40th St.",
  zip: 98052
},
salary: 1000000
}
```

The leaf property `streetNo` within the nested object `address` will be represented in the analytical store schema as a column `address.object.streetNo.int32`. The datatype is added as a suffix to the column. This way, if another document is added to the transactional store where the value of leaf property `streetNo` is "123" (note it’s a string), the schema of the analytical store automatically evolves without altering the type of a previously written column. A new column added to the analytical store as `address.object.streetNo.string` where this value of "123" is stored.

Data type to suffix map

Here is a map of all the property data types and their suffix representations in the analytical store:

ORIGINAL DATA TYPE	SUFFIX	EXAMPLE
Double	".float64"	24.99
Array	".array"	["a", "b"]
Binary	".binary"	0
Boolean	".bool"	True
Int32	".int32"	123
Int64	".int64"	255486129307
Null	".null"	null
String	".string"	"ABC"
Timestamp	".timestamp"	Timestamp(0, 0)
DateTime	".date"	ISODate("2020-08-21T07:43:07.375Z")
ObjectId	".objectId"	ObjectId("5f3f7b59330ec25c132623a2")
Document	".object"	{"a": "a"}

Cost-effective archival of historical data

Data tiering refers to the separation of data between storage infrastructures optimized for different scenarios. Thereby improving the overall performance and cost-effectiveness of the end-to-end data stack. With analytical store, Azure Cosmos DB now supports automatic tiering of data from the transactional store to analytical store with different data layouts. With analytical store optimized in terms of storage cost compared to the transactional store, allows you to retain much longer horizons of operational data for historical analysis.

After the analytical store is enabled, based on the data retention needs of the transactional workloads, you can configure the 'Transactional Store Time to Live (Transactional TTL)' property to have records automatically deleted from the transactional store after a certain time period. Similarly, the 'Analytical Store Time To Live (Analytical TTL)' allows you to manage the lifecycle of data retained in the analytical store independent from the transactional store. By enabling analytical store and configuring TTL properties, you can seamlessly tier and define the data retention period for the two stores.

Global Distribution

If you have a globally distributed Azure Cosmos DB account, after you enable analytical store for a container, it will be available in all regions of that account. Any changes to operational data are globally replicated in all regions. You can run analytical queries effectively against the nearest regional copy of your data in Azure Cosmos DB.

Security

Authentication with the analytical store is the same as the transactional store for a given database. You can use primary or read-only keys for authentication. You can leverage linked service in Synapse Studio to prevent pasting the Azure Cosmos DB keys in the Spark notebooks. Access to this Linked Service is available to anyone who has access into the workspace.

Support for multiple Azure Synapse Analytics runtimes

The analytical store is optimized to provide scalability, elasticity, and performance for analytical workloads without any dependency on the compute run-times. The storage technology is self-managed to optimize your analytics workloads without manual efforts.

By decoupling the analytical storage system from the analytical compute system, data in Azure Cosmos DB analytical store can be queried simultaneously from the different analytics runtimes supported by Azure Synapse Analytics. As of today, Azure Synapse Analytics supports Apache Spark and serverless SQL pool with Azure Cosmos DB analytical store.

> **NOTE**
> You can only read from analytical store using Azure Synapse Analytics run time. You can write the data back to your transactional store as a serving layer.

Pricing

Analytical store follows a consumption-based pricing model where you are charged for:

- Storage: the volume of the data retained in the analytical store every month including historical data as defined by Analytical TTL.
- Analytical write operations: the fully managed synchronization of operational data updates to the analytical store from the transactional store (auto-sync)
- Analytical read operations: the read operations performed against the analytical store from Azure Synapse Analytics Spark pool and serverless SQL pool run times.

Analytical store pricing is separate from the transaction store pricing model. There is no concept of provisioned RUs in the analytical store. See Azure Cosmos DB pricing page, for full details on the pricing model for analytical store.

In order to get a high-level cost estimate to enable analytical store on an Azure Cosmos DB container, you can use the Azure Cosmos DB Capacity planner and get an estimate of your analytical storage and write operations costs. Analytical read operations costs depends on the analytics workload characteristics but as a high-level estimate, scan of 1 TB of data in analytical store typically results in 130,000 analytical read operations, and results in a cost of $0.065.

Analytical Time-to-Live (TTL)

Analytical TTL indicates how long data should be retained in your analytical store, for a container.

If analytical store is enabled, inserts, updates, deletes to operational data are automatically synced from transactional store to analytical store, irrespective of the transactional TTL configuration. The retention of this operational data in the analytical store can be controlled by the Analytical TTL value at the container level, as specified below:

Analytical TTL on a container is set using the `AnalyticalStoreTimeToLiveInSeconds` property:

- If the value is set to "0", missing (or set to null): the analytical store is disabled and no data is replicated from transactional store to analytical store
- If present and the value is set to "-1": the analytical store retains all historical data, irrespective of the retention of the data in the transactional store. This setting indicates that the analytical store has infinite retention of your operational data
- If present and the value is set to some positive number "n": items will expire from the analytical store "n" seconds after their last modified time in the transactional store. This setting can be leveraged if you want to

retain your operational data for a limited period of time in the analytical store, irrespective of the retention of the data in the transactional store

Some points to consider:

- After the analytical store is enabled with an analytical TTL value, it can be updated to a different valid value later.
- While transactional TTL can be set at the container or item level, analytical TTL can only be set at the container level currently.
- You can achieve longer retention of your operational data in the analytical store by setting analytical TTL >= transactional TTL at the container level.
- The analytical store can be made to mirror the transactional store by setting analytical TTL = transactional TTL.

When you enable analytical store on a container:

- From the Azure portal, the analytical TTL option is set to the default value of -1. You can change this value to 'n' seconds, by navigating to container settings under Data Explorer.
- From the Azure SDK or PowerShell or CLI, the analytical TTL option can be enabled by setting it to either -1 or 'n'.

To learn more, see how to configure analytical TTL on a container.

Azure Synapse Link for Azure Cosmos DB supported features

12/4/2020 • 2 minutes to read • Edit Online

This article describes the functionalities that are currently supported in Azure Synapse Link for Azure Cosmos DB.

Azure Synapse support

There are two types of containers in Azure Cosmos DB:

- HTAP container - A container with Synapse Link enabled. This container has both transactional store and analytical store.
- OLTP container - A container with Synaspe Link not enabled. This container has only transactional store and no analytical store.

> **IMPORTANT**
> Azure Synapse Link for Azure Cosmos DB is currently supported in Synapse workspaces that do not have managed virtual network enabled.

You can connect to an Azure Cosmos DB container without enabling Synapse Link. In this scenario, you can only read/write to the transactional store. What follows is a list of the currently supported features within Synapse Link for Azure Cosmos DB.

CATEGORY	DESCRIPTION	APACHE SPARK POOL	SERVERLESS SQL POOL
Run-time Support	Supported Azure Synapse runtime to access Azure Cosmos DB	✓	Preview
Azure Cosmos DB API support	Supported Azure Cosmos DB API kind	SQL / MongoDB	SQL / MongoDB
Object	Objects such as a table that can be created, pointing directly to Azure Cosmos DB container	Dataframe, View, Table	View
Read	Type of Azure Cosmos DB container that can be read	OLTP / HTAP	HTAP
Write	Can the Azure Synapse runtime be used to write data to an Azure Cosmos DB container	Yes	No

- If you write data into an Azure Cosmos DB container from Spark, this process happens through the transactional store of Azure Cosmos DB. It will impact the transactional performance of Azure Cosmos DB by consuming Request Units.
- Dedicated SQL pool integration through external tables is currently not supported.

Supported code-generated actions for Spark

GESTURE	DESCRIPTION	OLTP	HTAP
Load to DataFrame	Load and read data into a Spark DataFrame	✓	✓
Create Spark table	Create a table pointing to an Azure Cosmos DB container	✓	✓
Write DataFrame to container	Write data into a container	✓	✓
Load streaming DataFrame from container	Stream data using Azure Cosmos DB change feed	✓	✓
Write streaming DataFrame to container	Stream data using Azure Cosmos DB change feed	✓	✓

Supported code-generated actions for serverless SQL pool

GESTURE	DESCRIPTION	OLTP	HTAP
Explore data	Explore data from a container with familiar T-SQL syntax and automatic schema inference	X	✓
Create views and build BI reports	Create a SQL view to have direct access to a container for BI through serverless SQL pool	X	✓
Join disparate data sources along with Cosmos DB data	Store results of query reading data from Cosmos DB containers along with data in Azure Blob Storage or Azure Data Lake Storage using CETAS	X	✓

Azure Synapse Link for Azure Cosmos DB: Near real-time analytics use cases

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API Azure Cosmos DB API for MongoDB

Azure Synapse Link for Azure Cosmos DB is a cloud native hybrid transactional and analytical processing (HTAP) capability that enables you to run near real-time analytics over operational data. Synapse Link creates a tight seamless integration between Azure Cosmos DB and Azure Synapse Analytics.

You might be curious to understand what industry use cases can leverage this cloud native HTAP capability for near real-time analytics over operational data. Here are three common use cases for Azure Synapse Link for Azure Cosmos DB:

- Supply chain analytics, forecasting & reporting
- Real-time personalization
- Predictive maintenance, anomaly detection in IOT scenarios

> **NOTE**
> Azure Synapse Link for Azure Cosmos DB targets the scenario where enterprise teams are looking to run near real-time analytics. These analytics are run without ETL over operational data generated across transactional applications built on Azure Cosmos DB. This does not replace the need for a separate data warehouse when there are traditional data warehouse requirements such as workload management, high concurrency, persistence aggregates across multiple data sources.

Supply chain analytics, forecasting & reporting

Research studies show that embedding big data analytics in supply chain operations leads to improvements in order-to-cycle delivery times and supply chain efficiency.

Manufacturers are onboarding to cloud-native technologies to break out of constraints of legacy Enterprise Resource Planning (ERP) and Supply Chain Management (SCM) systems. With supply chains generating increasing volumes of operational data every minute (order, shipment, transaction data), manufacturers need an operational database. This operational database should scale to handle the data volumes as well as an analytical platform to get to a level of real-time contextual intelligence to stay ahead of the curve.

The following architecture shows the power of leveraging Azure Cosmos DB as the cloud-native operational database and Synapse Link in supply chain analytics:

Based on previous architecture, you can achieve the following use cases with Synapse Link for Azure Cosmos DB:

- **Prepare & train predictive pipeline:** Generate insights over the operational data across the supply chain using machine learning translates. This way you can lower inventory, operations costs, and reduce the order-to-delivery times for customers.

  Synapse Link allows you to analyze the changing operational data in Azure Cosmos DB without any manual ETL processes. It saves you from additional cost, latency, and operational complexity. Synapse Link enables data engineers and data scientists to build robust predictive pipelines:

  - Query operational data from Azure Cosmos DB analytical store by leveraging native integration with Apache Spark pools in Azure Synapse Analytics. You can query the data in an interactive notebook or scheduled remote jobs without complex data engineering.
  - Build Machine Learning (ML) models with Spark ML algorithms and Azure ML integration in Azure Synapse Analytics.
  - Write back the results after model inference into Azure Cosmos DB for operational near-real-time scoring.

- **Operational reporting:** Supply chain teams need flexible and custom reports over real-time, accurate operational data. These reports are required to obtain a snapshot view of supply chain effectiveness, profitability, and productivity. It allows data analysts and other key stakeholders to constantly reevaluate the business and identify areas to tweak to reduce operational costs.

  Synapse Link for Azure Cosmos DB enables rich business intelligence (BI)/reporting scenarios:

  - Query operational data from Azure Cosmos DB analytical store by using native integration with serverless SQL pool and full expressiveness of T-SQL language.
  - Model and publish auto refreshing BI dashboards over Azure Cosmos DB through serverless SQL pool support for familiar BI tools. For example, Azure Analysis Services, Power BI Premium, etc.

The following is some guidance for data integration for batch & streaming data into Azure Cosmos DB:

- **Batch data integration & orchestration:** With supply chains getting more complex, supply chain data platforms need to integrate with variety of data sources and formats. Azure Synapse comes built-in with the same data integration engine and experiences as Azure Data Factory. This integration allows data engineers to create rich data pipelines without a separate orchestration engine:

- Move data from 85+ supported data sources to Azure Cosmos DB with Azure Data Factory.
- Write code-free ETL pipelines to Azure Cosmos DB including relational-to-hierarchical and hierarchical-to-hierarchical mappings with mapping data flows.

- **Streaming data integration & processing:** With the growth of Industrial IoT (sensors tracking assets from 'floor-to-store', connected logistics fleets, etc.), there is an explosion of real-time data being generated in a streaming fashion that needs to be integrated with traditional slow moving data for generating insights. Azure Stream Analytics is a recommended service for streaming ETL and processing on Azure with a wide range of scenarios. Azure Stream Analytics supports Azure Cosmos DB as a native data sink.

Real-time personalization

Retailers today must build secure and scalable e-commerce solutions that meet the demands of both customers and business. These e-commerce solutions need to engage customers through customized products and offers, process transactions quickly and securely, and focus on fulfillment and customer service. Azure Cosmos DB along with the latest Synapse Link for Azure Cosmos DB allows retailers to generate personalized recommendations for customers in real time. They use low-latency and tunable consistency settings for immediate insights as shown in the following architecture:

Synapse Link for Azure Cosmos DB use case:

- **Prepare & train predictive pipeline:** You can generate insights over the operational data across your business units or customer segments using Synapse Spark and machine learning models. This translates to personalized delivery to target customer segments, predictive end-user experiences and targeted marketing to fit your end-user requirements.

IOT predictive maintenance

Industrial IOT innovations have drastically reduced downtimes of machinery and increased overall efficiency across all fields of industry. One of such innovations is predictive maintenance analytics for machinery at the edge of the cloud.

The following is an architecture leveraging the cloud native HTAP capabilities of Azure Synapse Link for Azure Cosmos DB in IoT predictive maintenance:

Synapse Link for Azure Cosmos DB use cases:

- **Prepare & train predictive pipeline:** The historical operational data from IoT device sensors could be used to train predictive models such as anomaly detectors. These anomaly detectors are then deployed back to the edge for real-time monitoring. Such a virtuous loop allows for continuous retraining of the predictive models.
- **Operational reporting:** With the growth of digital twin initiatives, companies are collecting vast amounts of operational data from large number of sensors to build a digital copy of each machine. This data powers BI needs to understand trends over historical data in addition to real-time applications over recent hot data.

Sample scenario: HTAP for Azure Cosmos DB

For nearly a decade, Azure Cosmos DB has been used by thousands of customers for mission critical applications that require elastic scale, turnkey global distribution, multi-region write replication for low latency and high availability of both reads & writes in their transactional workloads.

The following list shows an overview of the various workload patterns that are supported with operational data using Azure Cosmos DB:

- Real-time apps & services
- Event stream processing
- BI dashboards
- Big data analytics
- Machine learning

Azure Synapse Link enables Azure Cosmos DB to not just power transactional workloads but also perform near real-time analytical workloads over historical operational data. It happens with no ETL requirements and guaranteed performance isolation from the transactional workloads.

The following image shows workload patterns using Azure Cosmos DB:

Let us take the example of an e-commerce company CompanyXYZ with global operations across 20 countries/regions to illustrate the benefits of choosing Azure Cosmos DB as the single real-time database powering both transactional and analytical requirements of an inventory management platform.

- CompanyXYZ's core business depends on the inventory management system – hence availability & reliability are core pillar requirements. Benefits of using Azure Cosmos DB:
  - By virtue of deep integration with Azure infrastructure, and transparent multi-region writes, global replication, Azure Cosmos DB provides industry-leading 99.999% high availability against regional outages.
- CompanyXYZ's supply chain partners may be in separate geographic locations but they may have to see a single view of the product inventory across the globe to support their local operations. This includes the need to be able to read updates made by other supply chain partners in real time. As well as being able to make updates without worrying about conflicts with other partners at high throughput. Benefits of using Azure Cosmos DB:
  - With its unique multi-region writes replication protocol and latch-free, write-optimized transactional store, Azure Cosmos DB guarantees less than 10-ms latencies for both indexed reads and writes at the 99th percentile globally.
  - High throughput ingestion of both batch & streaming data feeds with real-time indexing in transactional store.
  - Azure Cosmos DB transactional store provides three more options than the two extremes of strong and eventual consistency levels to achieve the availability vs performance tradeoffs closest to the business need.
- CompanyXYZ's supply chain partners have highly fluctuating traffic patterns ranging from hundreds to millions of requests/s and thus the inventory management platform needs to deal with unexpected burstiness in traffic. Benefits of using Azure Cosmos DB:
  - Azure Cosmos DB's transactional store supports elastic scalability of storage and throughput using horizontal partitioning. Containers and databases configured in Autopilot mode can automatically and instantly scale the provisioned throughput based on the application needs without impacting the availability, latency, throughput, or performance of the workload globally.
- CompanyXYZ needs to establish a secure analytics platform to house system-wide historical inventory data to enable analytics and insights across supply chain partner, business units and functions. The analytics platform needs to enable collaboration across the system, traditional BI/reporting use cases, advanced analytics use cases and predictive intelligent solutions over the operational inventory data. Benefits of using

Synapse Link for Azure Cosmos DB:

- By using Azure Cosmos DB analytical store, a fully isolated column store, Synapse Link enables no Extract-Transform-Load (ETL) analytics in Azure Synapse Analytics against globally distributed operational data at scale. Business analysts, data engineers and data scientists can now use Synapse Spark or Synapse SQL in an interoperable manner to run near real-time business intelligence, analytics, and machine learning pipelines without impacting the performance of their transactional workloads on Azure Cosmos DB. See the benefits of Synapse Link in Azure Cosmos DB for more details.

Frequently asked questions about Azure Synapse Link for Azure Cosmos DB

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API Azure Cosmos DB API for MongoDB

Azure Synapse Link for Azure Cosmos DB creates a tight integration between Azure Cosmos DB and Azure Synapse Analytics. It enables customers to run near real-time analytics over their operational data with full performance isolation from their transactional workloads and without an ETL pipeline. This article answers commonly asked questions about Synapse Link for Azure Cosmos DB.

General FAQ

Is Azure Synapse Link supported for all Azure Cosmos DB APIs?

Azure Synapse Link is supported for the Azure Cosmos DB SQL (Core) API and for the Azure Cosmos DB API for MongoDB.

Is Azure Synapse Link supported for multi-region Azure Cosmos DB accounts?

Yes, for multi-region Azure Cosmos accounts, the data stored in the analytical store is also globally distributed. Regardless of single write region or multiple write regions, analytical queries performed from Azure Synapse Analytics can be served from the closest local region.

When planning to configure a multi-region Azure Cosmos DB account with analytical store support, it is recommended to have all the necessary regions added at time of account creation.

Can I choose to enable Azure Synapse Link for only certain region and not all regions in a multi-region account set-up?

When Azure Synapse Link is enabled for a multi-region account, the analytical store is created in all regions. The underlying data is optimized for throughput and transactional consistency in the transactional store.

Is backup and restore supported for Azure Synapse Link enabled accounts?

For the containers with analytical store turned on, automatic backup and restore of your data in the analytical store is not supported at this time.

When Synapse Link is enabled on a database account, Azure Cosmos DB will continue to automatically take backups of your data in the transactional store (only) of containers at scheduled backup interval, as always. It is important to note that when a container with analytical store turned on is restored to a new account, the container will be restored with only transactional store and no analytical store enabled.

Can I disable the Azure Synapse Link feature for my Azure Cosmos DB account?

Currently, after the Synapse Link capability is enabled at the account level, you cannot disable it. Understand that you will not have any billing implications if the Synapse Link capability is enabled at the account level and there is no analytical store enabled containers.

If you need to turn off the capability, you have 2 options. The first one is to delete and re-create a new Azure Cosmos DB account, migrating the data if necessary. The second option is to open a support ticket, to get help on a data migration to another account.

Does analytical store have any impact on Cosmos DB transactional SLAs?

No, there is no impact.

Azure Cosmos DB analytical store

Can I enable analytical store on existing containers?

Currently, the analytical store can only be enabled for new containers (both in new and existing accounts).

Can I disable analytical store on my Azure Cosmos DB containers after enabling it during container creation?

Currently, the analytical store cannot be disabled on an Azure Cosmos DB container after it is enabled during container creation.

Is analytical store supported for Azure Cosmos DB containers with autoscale provisioned throughput?

Yes, the analytical store can be enabled on containers with autoscale provisioned throughput.

Is there any effect on Azure Cosmos DB transactional store provisioned RUs?

Azure Cosmos DB guarantees performance isolation between the transactional and analytical workloads. Enabling the analytical store on a container will not impact the RU/s provisioned on the Azure Cosmos DB transactional store. The transactions (read & write) and storage costs for the analytical store will be charged separately. See the pricing for Azure Cosmos DB analytical store for more details.

Are delete and update operations on the transactional store reflected in the analytical store?

Yes, deletes and updates to the data in the transactional store will be reflected in the analytical store. You can configure the Time to Live (TTL) on the container to include historical data so that the analytical store retains all versions of items that satisfy the analytical TTL criteria. See the overview of analytical TTL for more details.

Can I connect to analytical store from analytics engines other than Azure Synapse Analytics?

You can only access and run queries against the analytical store using the various run-times provided by Azure Synapse Analytics. The analytical store can be queried and analyzed using:

- Synapse Spark with full support for Scala, Python, SparkSQL, and C#. Synapse Spark is central to data engineering and science scenarios
- Serverless SQL pool with T-SQL language and support for familiar BI tools (For example, Power BI Premium, etc.)

Can I connect to analytical store from Synapse SQL provisioned?

At this time, the analytical store cannot be accessed from Synapse SQL provisioned.

Can I write back the query aggregation results from Synapse back to the analytical store?

Analytical store is a read-only store in an Azure Cosmos DB container. So, you cannot directly write back the aggregation results to the analytical store, but can write them to the Azure Cosmos DB transactional store of another container, which can later be leveraged as a serving layer.

Is the autosync replication from transactional store to the analytical store asynchronous or synchronous and what are the latencies?

Auto-sync latency is usually within 2 minutes. In cases of shared throughput database with a large number of containers, auto-sync latency of individual containers could be higher and take up to 5 minutes. We would like to learn more how this latency fits your scenarios. For that, please reach out to the Azure Cosmos DB team.

Are there any scenarios where the items from the transactional store are not automatically propagated to the analytical store?

If specific items in your container violate the well-defined schema for analytics, they will not be included in the analytical store. If you have scenarios blocked by well-defined schema for analytics, email the Azure Cosmos DB team for help.

Can I partition the data in analytical store differently from transactional store?

The data in analytical store is partitioned based on the horizontal partitioning of shards in the transactional store. Currently, you cannot choose a different partitioning strategy for the analytical store.

Can I customize or override the way transactional data is transformed into columnar format in the analytical store?

Currently you can't transform the data items when they are automatically propagated from the transactional store to analytical store. If you have scenarios blocked by this limitation, email the Azure Cosmos DB team.

Is analytical store supported by Terraform?

Currently Terraform doesn't support analytical store containers. Please check Terraform GitHub Issues for more information.

Analytical Time to live (TTL)

Is TTl for analytical data supported at both container and item level?

At this time, TTl for analytical data can only be configured at container level and there is no support to set analytical TTL at item level.

After setting the container level analytical TTL on an Azure Cosmos DB container, can I change to a different value later?

Yes, analytical TTL can be updated to any valid value. See the Analytical TTL article for more details about analytical TTL.

Can I update or delete an item from the analytical store after it has been TTL'd out from the transactional store?

All transactional updates and deletes are copied to the analytical store but if the item has been purged from the transactional store, then it cannot be updated in the analytical store. To learn more, see the Analytical TTL article.

Billing

What is the billing model of Azure Synapse Link for Azure Cosmos DB?

The billing model of Azure Synapse Link includes the costs incurred by using the Azure Cosmos DB analytical store and the Synapse runtime. To learn more, see the Azure Cosmos DB analytical store pricing and Azure Synapse Analytics pricing articles.

What is the billing impact if I enable Synapse Link in my Azure Cosmos DB database account?

None. You will only be charged when you create an analytical store enabled container and start to load data.

Security

What are the ways to authenticate with the analytical store?

Authentication with the analytical store is the same as a transactional store. For a given database, you can authenticate with the primary or read-only key. You can leverage linked service in Azure Synapse Studio to prevent pasting the Azure Cosmos DB keys in the Spark notebooks. Access to this Linked Service is available for everyone who has access to the workspace.

Synapse run-times

What are the currently supported Synapse run-times to access Azure Cosmos DB analytical store?

AZURE SYNAPSE RUNTIME	CURRENT SUPPORT
Azure Synapse Spark pools	Read, Write (through transactional store), Table, Temporary View
Azure Synapse serverless SQL pool	Read, View

AZURE SYNAPSE RUNTIME	CURRENT SUPPORT
Azure Synapse SQL Provisioned	Not available

Do my Azure Synapse Spark tables sync with my Azure Synapse serverless SQL pool tables the same way they do with Azure Data Lake?

Currently, this feature is not available.

Can I do Spark structured streaming from analytical store?

Currently Spark structured streaming support for Azure Cosmos DB is implemented using the change feed functionality of the transactional store and it's not yet supported from analytical store.

Azure Synapse Studio

In the Azure Synapse Studio, how do I recognize if I'm connected to an Azure Cosmos DB container with the analytics store enabled?

An Azure Cosmos DB container enabled with analytical store has the following icon:

A transactional store container will be represented with the following icon:

How do you pass Azure Cosmos DB credentials from Azure Synapse Studio?

Currently Azure Cosmos DB credentials are passed while creating the linked service by the user who has access to the Azure Cosmos DB databases. Access to that store is available to other users who have access to the workspace.

Plan and manage costs for Azure Cosmos DB

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

This article describes how you can plan and manage costs for Azure Cosmos DB. First, you use the Azure Cosmos DB capacity calculator to estimate your workload cost before you create any resources. Later you can review the estimated cost and start creating your resources.

After you've started using Azure Cosmos DB resources, use the Cost Management features to set budgets and monitor costs. You can also review forecasted costs and identify spending trends to identify areas where you might want to act. The costs for Azure Cosmos DB are only a portion of the monthly costs in your Azure bill. Although this article explains how to plan for and manage costs for Azure Cosmos DB, you're billed for all Azure services and resources used in your Azure subscription, including the third-party services.

Prerequisites

Provisioned throughput or serverless

Azure Cosmos DB supports two types of capacity modes: provisioned throughput and serverless. The way you get charged for your Azure Cosmos DB usage varies a lot between these two modes, so it's important to choose the one that works best for your workload. See the how to choose between provisioned throughput and serverless article for guidance and recommendations on how to make this choice.

Cost analysis

Cost analysis in Cost Management supports most Azure account types, but not all of them. To view the full list of supported account types, see Understand Cost Management data. To view cost data, you need at least read access for an Azure account. For information about assigning access to Azure Cost Management data, see Assign access to data.

Estimating provisioned throughput costs before using Azure Cosmos DB

If you plan to use Azure Cosmos DB in provisioned throughput mode, use the Azure Cosmos DB capacity calculator to estimate costs before you create the resources in an Azure Cosmos account. The capacity calculator is used to get an estimate of the required throughput and cost of your workload. Configuring your Azure Cosmos databases and containers with the right amount of provisioned throughput, or Request Units (RU/s), for your workload is essential to optimize the cost and performance. You have to input details such as API type, number of regions, item size, read/write requests per second, total data stored to get a cost estimate. To learn more about the capacity calculator, see the estimate article.

The following screenshot shows the throughput and cost estimation by using the capacity calculator:

Estimating serverless costs before using Azure Cosmos DB

If you plan to use Azure Cosmos DB in serverless mode, you need to estimate how many Request Units and GB of storage you may consume on a monthly basis. You can estimate the required amount of Request Units by evaluating the number of database operations that would be issued in a month, and multiply their amount by their corresponding RU cost. The following table lists estimated RU charges for common database operations:

OPERATION	ESTIMATED COST	NOTES
Create an item	5 RUs	Average cost for a 1 KB item with less than 5 properties to index
Update an item	10 RUs	Average cost for a 1 KB item with less than 5 properties to index
Read an individual item by its ID and partition key (point-read)	1 RU	Average cost for a 1 KB item
Delete an item	5 RUs	
Execute a query	10 RUs	Average cost for a query that takes full advantage of indexing and returns 100 results or less

> **IMPORTANT**
>
> Pay attention to the Notes from the table above. For a more accurate estimation of the actual costs of your operations, you can use the Azure Cosmos DB Emulator and measure the exact RU cost of your operations. Although the Azure Cosmos DB Emulator doesn't support serverless, it reports a standard RU charge for database operations and can be used for this estimation.

Once you have computed the total number of Request Units and GB of storage you're likely to consume over a month, the following formula will return your cost estimate: **([Number of Request units] / 1,000,000 * $0.25) + ([GB of storage] * $0.25)**.

> **NOTE**
>
> The costs shown in the previous example are for demonstration purposes only. See the pricing page for the latest pricing information.

Review estimated costs in the Azure portal

As you start using Azure Cosmos DB resources from Azure portal, you can see the estimated costs. Use the following steps to review the cost estimate:

1. Sign into the Azure portal and navigate to your Azure Cosmos account.
2. Go to the **Overview** section.
3. Check the **Cost** chart at the bottom. This chart shows an estimate of your current cost over a configurable time period:
4. Create a new container such as a graph container.
5. Input the throughput required for your workload such as 400 RU/s. After you input the throughput value, you can see the pricing estimate as shown in the following screenshot:

If your Azure subscription has a spending limit, Azure prevents you from spending over your credit amount. As you

create and use Azure resources, your credits are used. When you reach your credit limit, the resources that you deployed are disabled for the rest of that billing period. You can't change your credit limit, but you can remove it. For more information about spending limits, see Azure spending limit.

You can pay for Azure Cosmos DB charges with your Azure Enterprise Agreement monetary commitment credit. However, you can't use the monetary commitment credit to pay for charges for third party products and services including those from the Azure Marketplace.

Monitor costs

As you use resources with Azure Cosmos DB, you incur costs. Resource usage unit costs vary by time intervals (seconds, minutes, hours, and days) or by request unit usage. As soon as usage of Azure Cosmos DB starts, costs are incurred and you can see them in the cost analysis pane in the Azure portal.

When you use cost analysis, you can view the Azure Cosmos DB costs in graphs and tables for different time intervals. Some examples are by day, current, prior month, and year. You can also view costs against budgets and forecasted costs. Switching to longer views over time can help you identify spending trends and see where overspending might have occurred. If you’ve created budgets, you can also easily see where they exceeded.

To view Azure Cosmos DB costs in cost analysis:

1. Sign into the Azure portal.
2. Open the scope in the Azure portal and select **Cost analysis** in the menu. For example, go to **Subscriptions**, select a subscription from the list, and then select **Cost analysis** in the menu. Select **Scope** to switch to a different scope in cost analysis.
3. By default, cost for all services are shown in the first donut chart. Select the area in the chart labeled "Azure Cosmos DB".
4. To narrow costs for a single service such as Azure Cosmos DB, select **Add filter** and then select **Service name**. Then, choose **Azure Cosmos DB** from the list. Here’s an example showing costs for just Azure Cosmos DB:

In the preceding example, you see the current cost for Azure Cosmos DB for the month of Feb. The charts also contain Azure Cosmos DB costs by location and by resource group.

Create budgets

You can create budgets to manage costs and create alerts that automatically notify stakeholders of spending anomalies and overspending risks. Alerts are based on spending compared to budget and cost thresholds. Budgets and alerts are created for Azure subscriptions and resource groups, so they're useful as part of an overall cost monitoring strategy.

Budgets can be created with filters for specific resources or services in Azure if you want more granularity present in your monitoring. Filters help ensure that you don't accidentally create new resources that cost you additional money. For more about the filter options when you when create a budget, see Group and filter options.

Export cost data

You can also export your cost data to a storage account. This is helpful when you need or others to do additional data analysis for costs. For example, a finance teams can analyze the data using Excel or Power BI. You can export your costs on a daily, weekly, or monthly schedule and set a custom date range. Exporting cost data is the recommended way to retrieve cost datasets.

Pricing model in Azure Cosmos DB

11/2/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

The pricing model of Azure Cosmos DB simplifies the cost management and planning. With Azure Cosmos DB, you pay for the operations you perform against the database and for the storage consumed by your data.

- **Database operations**: The way you get charged for your database operations depends on the type of Azure Cosmos account you are using.
  - **Provisioned Throughput**: Provisioned throughput (also called reserved throughput) provides high performance at any scale. You specify the throughput that you need in Request Units per second (RU/s), and Azure Cosmos DB dedicates the resources required to provide the configured throughput. You can provision throughput on either a database or a container. Based on your workload needs, you can scale throughput up/down at any time or use autoscale (although there is a minimum throughput required on a database or a container to guarantee the SLAs). You are billed hourly for the maximum provisioned throughput for a given hour.

> **NOTE**
> Because the provisioned throughput model dedicates resources to your container or database, you will be charged for the throughput you have provisioned even if you don't run any workloads.

  - **Serverless**: In serverless mode, you don't have to provision any throughput when creating resources in your Azure Cosmos account. At the end of your billing period, you get billed for the amount of Request Units that has been consumed by your database operations.
- **Storage**: You are billed a flat rate for the total amount of storage (in GBs) consumed by your data and indexes for a given hour. Storage is billed on a consumption basis, so you don't have to reserve any storage in advance. You are billed only for the storage you consume.

The pricing model in Azure Cosmos DB is consistent across all APIs. For more information, see the Azure Cosmos DB pricing page, Understanding your Azure Cosmos DB bill and How Azure Cosmos DB pricing model is cost-effective for customers.

If you deploy your Azure Cosmos DB account to a non-government region in the US, there is a minimum price for both database and container-based throughput in provisioned throughput mode. There is no minimum price in serverless mode. The pricing varies depending on the region you are using, see the Azure Cosmos DB pricing page for latest pricing information.

Try Azure Cosmos DB for free

Azure Cosmos DB offers many options for developers to it for free. These options include:

- **Azure Cosmos DB free tier**: Azure Cosmos DB free tier makes it easy to get started, develop and test your applications, or even run small production workloads for free. When free tier is enabled on an account, you'll get the first 400 RU/s and 5 GB of storage in the account free, for the lifetime of the account. You can have up to one free tier account per Azure subscription and must opt-in when creating the account. To get started, create a new account in Azure portal with free tier enabled or use an ARM Template.
- **Azure free account**: Azure offers a free tier that gives you $200 in Azure credits for the first 30 days and a

limited quantity of free services for 12 months. For more information, see Azure free account. Azure Cosmos DB is a part of Azure free account. Specifically for Azure Cosmos DB, this free account offers 5-GB storage and 400 RU/s of provisioned throughput for the entire year.

- **Try Azure Cosmos DB for free**: Azure Cosmos DB offers a time-limited experience by using try Azure Cosmos DB for free accounts. You can create an Azure Cosmos DB account, create database and collections and run a sample application by using the Quickstarts and tutorials. You can run the sample application without subscribing to an Azure account or using your credit card. Try Azure Cosmos DB for free offers Azure Cosmos DB for one month, with the ability to renew your account any number of times.
- **Azure Cosmos DB emulator**: Azure Cosmos DB emulator provides a local environment that emulates the Azure Cosmos DB service for development purposes. Emulator is offered at no cost and with high fidelity to the cloud service. Using Azure Cosmos DB emulator, you can develop and test your applications locally, without creating an Azure subscription or incurring any costs. You can develop your applications by using the emulator locally before going into production. After you are satisfied with the functionality of the application against the emulator, you can switch to using the Azure Cosmos DB account in the cloud and significantly save on cost. For more information about emulator, see Using Azure Cosmos DB for development and testing article for more details.

Pricing with reserved capacity

Azure Cosmos DB reserved capacity helps you save money when using the provisioned throughput mode by pre-paying for Azure Cosmos DB resources for either one year or three years. You can significantly reduce your costs with one-year or three-year upfront commitments and save between 20-65% discounts when compared to the regular pricing. Azure Cosmos DB reserved capacity helps you lower costs by pre-paying for the provisioned throughput (RU/s) for a period of one year or three years and you get a discount on the throughput provisioned.

Reserved capacity provides a billing discount and does not affect the runtime state of your Azure Cosmos DB resources. Reserved capacity is available consistently to all APIs, which includes MongoDB, Cassandra, SQL, Gremlin, and Azure Tables and all regions worldwide. You can learn more about reserved capacity in Prepay for Azure Cosmos DB resources with reserved capacity article and buy reserved capacity from the Azure portal.

Total Cost of Ownership (TCO) with Azure Cosmos DB

11/2/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB is designed with the fine grained multi-tenancy and resource governance. This design allows Azure Cosmos DB to operate at significantly lower cost and help users save. Currently Azure Cosmos DB supports more than 280 customer workloads on a single machine with the density continuously increasing, and thousands of customer workloads within a cluster. It load balances replicas of customers' workloads across different machines in a cluster and across multiple clusters within a data center. To learn more, see Azure Cosmos DB: Pushing the frontier of globally distributed databases. Because of resource-governance, multi-tenancy, and native integration with the rest of Azure infrastructure, Azure Cosmos DB is on average 4 to 6 times cheaper than MongoDB, Cassandra, or other OSS NoSQL running on IaaS and up to 10 times cheaper than the database engines running on premises. See the paper on The total cost of (non) ownership of a NoSQL database cloud service.

The OSS NoSQL database solutions, such as Apache Cassandra, MongoDB, HBase, engines were designed for on-premises. When offered as a managed service they are equivalent to a Resource Manager template with a tenant database for managing the provisioned clusters and monitoring support. OSS NoSQL architectures require significant operational overhead, and the expertise can be difficult and expensive to find. On the other hand, Azure Cosmos DB is a fully managed cloud service, which allows developers to focus on business innovation rather than on managing and maintaining database infrastructure.

Unlike a cloud-native database service Azure Cosmos DB, OSS NoSQL database engines were not designed and built with the resource governance or fine-grained multi-tenancy as the fundamental architectural principles. OSS NoSQL database engines like Cassandra and MongoDB make a fundamental assumption that all the resources of the virtual machine on which they are running are available for their use. Many of these database engines cannot function if the amount of resources drops below a certain threshold. For example, for small VM instances, and they are available with vendor-recommended configurations suggesting typically large-scale VMs with higher cost. So, it is not possible to host an OSS NoSQL or any other on-premises database engine and make it available by using a consumption-based charging model like requests per second or consumed storage.

Total cost of ownership of Azure Cosmos DB

The serverless provisioning model of Azure Cosmos DB eliminates the need to over-provision the database infrastructure. Azure Cosmos DB resources are provided without any need for specialized configurations or licensing. As a result, the Azure Cosmos DB-backed applications can run with as much as a 70 percent Total cost of ownership savings when compared to OSS NoSQL databases. For some real-time examples, see customer use-cases. Other benefits of the Azure Cosmos DB pricing model include:

- **Great value for the price:** Market analysts, customers, and partners have confirmed a greater value of all the features that Azure Cosmos DB offers for a much lower price compared to what customers can get when implementing these solutions on their own or through other vendors. The database features such global distribution, multi-region writes, well-defined and intuitive consistency models, automatic indexing are greatly simplified with Azure Cosmos DB without any complexity, overhead, or downtime.
- **No NoSQL DevOps administration is required:** With Azure Cosmos DB one does not need to employ DevOps to manage deployments, perform maintenance, scale, or patch. You can execute the all the workloads that you would do with OSS NoSQL cluster hosted on-premises or on cloud infrastructure.

- **Ability to elastically scale:** Azure Cosmos DB throughput can be scaled up and down, allowing you to reduce the cost of ownership during non-peak times. OSS NoSQL clusters deployed on cloud infrastructure offer limited elasticity, and on-premises deployments aren't elastic by definition. In Azure Cosmos DB, if you provision more throughput, your throughput is guaranteed to scale linearly. This guarantee is backed up by financial SLAs and at the 99th percentile at any scale.

- **Economies of scale:** A managed service like Azure Cosmos DB operates with a large number of nodes, integrated natively with networking, storage, and computes. Because of Azure Cosmos DB's large scale, standardization you can save costs.

- **Optimized for the cloud:** Azure Cosmos DB is designed from the ground-up with fine-grained multi-tenancy and performance isolation. This allows for optimally placing, executing, and balancing thousands of tenants and their workloads across clusters and data centers. In contrast, the current generation of OSS NoSQL databases operate on-premises with the entire virtual machine assumed to run a single tenant's workload. These databases are also not designed to leverage a cloud provider's infrastructure and hardware to the full extent. For example, an OSS NoSQL database engine isn't aware of the differences between a virtual machine being down Vs a routine image upgrade, or the fact that premium disk is already three-way replicated. It can't take advantage of these benefits and pass on the benefits and savings to customers.

- **You pay by the hour:** For large-scale workloads, that need to scale at any point in time, you are only charged by the hour. The workloads on an application typically vary across times of the year, and by the data that is queried. With Azure Cosmos DB, you can scale up or down as you need and pay only for what you need. With on-premises or IaaS-hosted systems, you can't match this model, because there isn't a way to decommission the hardware every hour. In such cases, you can potentially save between 10 to 14 times on an average with Azure Cosmos DB.

- **You get numerous features for free:** In Azure Cosmos DB, write workloads are substantially cheaper compared to alternative database services. In addition, Azure Cosmos DB offers features such as such as automatic indexing, Time to Live (TTL), Change Feed and others without any additional charges, something that other database services typically charge.

- **Uses unified currency for diverse workloads:** Unlike alternative offerings, in Azure Cosmos DB, you do not need to segment workloads, for example, into reads and writes. Or provision throughput on a per workload type that is read throughput vs. write throughput. In Azure Cosmos DB, provisioned throughput is reserved using a unified and normalized currency in terms of Request Units or RU/sec. Azure Cosmos DB

doesn't force you to assign priority to your workloads, perform capacity planning or pay for each type of capacity separately. Such approach enables you to easily interchange the same RU/s between various operations and workload types.

- **Doesn't require provisioning VMs to scale:** Most operational databases require you to go with large virtual machines to avoid noisy neighbors and for loose resource governance, if you want scale. This puts the burden and the upfront commitment of cost on the customers. With Azure Cosmos DB, you can start small and grow into the large scale workload sizes seamlessly, and without any downtime or impact on data availability.
- **You can utilize provisioned throughput to a maximum limit:** By the virtue of sub-core multiplexing in Azure Cosmos DB, you can saturate the provisioned throughput to a greater extent than IaaS hosted options or third party offers. This method saves a lot more than the alternative solutions.
- **Deep integration of Azure Cosmos DB with other Azure services.** Azure Cosmos DB has a native integration with Networking, Compute, Azure Functions (serverless), Azure IoT, and others Azure services. With this integration, you get the best performance, speed of data replication across the world with robust guarantees. The third party solutions won't be able to match or would typically charge a premium to offer such features.
- **You automatically get high availability, with at least 10-20 fault domains by default:** Azure Cosmos DB supports the distribution of workloads across fault domains, a feature that is critical for high availability. It offers 99.999 high availability for reads and writes at the 99th percentile across anywhere in the world. The cost of implementing something like this on your own or through a third-party solution, would be high.
- **You automatically get all enterprise capabilities, at no additional cost.** Azure Cosmos DB offers the most comprehensive set of compliance certifications, security, and encryption at rest and in motion at no additional cost (compared to our competition). You automatically get regional availability anywhere in the world. You can span your database across any number of Azure regions and add or remove regions at any point.
- **You can save up to 65% of costs with reserved capacity:** Azure Cosmos DB reserved capacity helps you save money by pre-paying for Azure Cosmos DB resources for either one year or three years. You can significantly reduce your costs with one-year or three-year upfront commitments and save between 20-65% discounts when compared to the regular pricing. On your mission-critical workloads you can get better SLAs in terms of provisioning capacity.

Understand your Azure Cosmos DB bill

12/4/2020 • 19 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

As a fully managed cloud-native database service, Azure Cosmos DB simplifies billing by charging only for your database operations and consumed storage. There are no additional license fees, hardware, utility costs, or facility costs compared to on-premises or IaaS-hosted alternatives. When you consider the multi region capabilities of Azure Cosmos DB, the database service provides a substantial reduction in costs compared to existing on-premises or IaaS solutions.

- **Database operations**: The way you get charged for your database operations depends on the type of Azure Cosmos account you are using.
  - **Provisioned Throughput**: You are billed hourly for the maximum provisioned throughput for a given hour, in increments of 100 RU/s.
  - **Serverless**: You are billed hourly for the total amount of Request Units consumed by your database operations.
- **Storage**: You are billed a flat rate for the total amount of storage (in GBs) consumed by your data and indexes for a given hour.

See the pricing page for the latest pricing information.

This article uses some examples to help you understand the details you see on the monthly bill. The numbers shown in the examples may be different if your Azure Cosmos containers have a different amount of throughput provisioned, if they span across multiple regions or run for a different for a period over a month. All the examples in this article calculate the bill based on the pricing information shown in the Pricing page.

> **NOTE**
> Billing is for any portion of a wall-clock hour, not a 60 minute duration. All the examples shown in this doc are based on the price for an Azure Cosmos account deployed in a non-government region in the US. The pricing and calculation vary depending on the region you are using, see the Azure Cosmos DB pricing page for latest pricing information.

Billing examples

Billing example - provisioned throughput on a container (full month)

- Let's assume you configure a throughput of 1,000 RU/sec on a container, and it exists for 24 hours * 30 days for the month = 720 hours total.
- 1,000 RU/sec is 10 units of 100 RU/sec per hour for each hour the containers exists (that is, 1,000/100 = 10).
- Multiplying 10 units per hour by the cost of $0.008 (per 100 RU/sec per hour) = $0.08 per hour.
- Multiplying the $0.08 per hour by the number of hours in the month equals $0.08 * 24 hours * 30 days = $57.60 for the month.
- The total monthly bill will show 7,200 units (of 100 RUs), which will cost $57.60.

Billing example - provisioned throughput on a container (partial month)

- Let's assume we create a container with provisioned throughput of 2,500 RU/sec. The container lives for 24 hours over the month (for example, we delete it 24 hours after we create it).
- Then we'll see 600 units on the bill (2,500 RU/sec / 100 RU/sec/unit * 24 hours). The cost will be $4.80 (600 units * $0.008/unit).
- Total bill for the month will be $4.80.

Billing example - serverless container

- Let's assume we create a serverless container.
- Over a month, we issue database requests consuming a total of 500,000 Request Units. The cost will be $0.125 (500,000 * $0.25/million).
- Total bill for the month will be $0.125.

Billing rate if storage size changes

Storage capacity is billed in units of the maximum hourly amount of data stored, in GB, over a monthly period. For example, if you utilized 100 GB of storage for half of the month and 50 GB for the second half of the month, you would be billed for an equivalent of 75 GB of storage during that month.

Billing rate when container or a set of containers are active for less than an hour

You're billed the flat rate for each hour the container or database exists, no matter the usage or if the container or database is active for less than an hour. For example, if you create a container or database and delete it 5 minutes later, your bill will include one hour.

Billing rate when provisioned throughput on a container or database scales up/down

If you increase provisioned throughput at 9:30 AM from 400 RU/sec to 1,000 RU/sec and then lower provisioned throughput at 10:45 AM back to 400 RU/sec, you will be charged for two hours of 1,000 RU/sec.

If you increase provisioned throughput for a container or a set of containers at 9:30 AM from 100-K RU/sec to 200-K RU/sec and then lower provisioned throughput at 10:45 AM back to 100-K RU/sec, you'll be charged for two hours of 200 K RU/sec.

Billing example: multiple containers, each with dedicated provisioned throughput mode

- If you create an Azure Cosmos account in East US 2 with two containers with provisioned throughput of 500 RU/sec and 700 RU/sec, respectively, you would have a total provisioned throughput of 1,200 RU/sec.
- You would be charged 1,200/100 *$0.008=$0.096/hour.
- If your throughput needs changed, and you've increased each container's capacity by 500 RU/sec while also creating a new unlimited container with 20,000 RU/sec, your overall provisioned capacity would be 22,200 RU/sec (1,000 RU/sec + 1,200 RU/sec + 20,000RU/sec).
- Your bill would then change to:$0.008x 222 =$1.776/hour.
- In a month of 720 hours (24 hours * 30 days), if for 500 hours provisioned throughput was 1,200 RU/sec and for the remaining 220 hours provisioned throughput was 22,200 RU/sec, your monthly bill shows: 500 x$0.096/hour + 220 x$1.776/hour =$438.72/month.

Billing example: containers with shared (provisioned) throughput mode

- If you create an Azure Cosmos account in East US 2 with two Azure Cosmos databases (with a set of containers sharing the throughput at the database level) with the provisioned throughput of 50-K RU/sec and 70-K RU/sec, respectively, you would have a total provisioned throughput of 120 K RU/sec.
- You would be charged 1200 x$0.008=$9.60/hour.
- If your throughput needs changed and you increased each database's provisioned throughput by 10K RU/sec for each database, and you add a new container to the first database with dedicated throughput mode of 15-K RU/sec to your shared throughput database, your overall provisioned capacity would be 155-K RU/sec (60 K RU/sec + 80 K RU/sec + 15 K RU/sec).
- Your bill would then change to: 1,550 *$0.008=$12.40/hour.
- In a month of 720 hours, if for 300 hours provisioned throughput was 120-K RU/sec and for the remaining 420 hours provisioned throughput was 155-K RU/sec, your monthly bill will show: 300 x$9.60/hour + 420 x$12.40/hour =$2,880+$5,208=$8,088/month.

Billing examples with geo-replication

You can add/remove Azure regions anywhere in the world to your Azure Cosmos database account at any time. The throughput that you have configured for various Azure Cosmos databases and containers will be reserved in each of the Azure regions associated with your Azure Cosmos database account. If the sum of provisioned throughput (RU/sec) configured across all the databases and containers within your Azure Cosmos database account (provisioned per hour) is T and the number of Azure regions associated with your database account is N, then the total provisioned throughput for a given hour, for your Azure Cosmos database account is equal to T x N RU/sec. Provisioned throughput (single write region) costs $0.008/hour per 100 RU/sec and provisioned throughput with multiple writable regions (multi-region writes config) costs $0.016/per hour per 100 RU/sec (see the Pricing page). Whether its single write region, or multiple write regions, Azure Cosmos DB allows you to read data from any region.

Billing example: multi-region Azure Cosmos account, single region writes

Let's assume you have an Azure Cosmos container in West US. The container is created with throughput 10K RU/sec and you store 1 TB of data this month. Let's assume you add three regions (East US, North Europe, and East Asia) to your Azure Cosmos account, each with the same storage and throughput. Your total monthly bill will be (assuming 30 days in a month). Your bill would be as follows:

ITEM	USAGE (MONTH)	RATE	MONTHLY COST
Throughput bill for container in West US	10K RU/sec * 24 * 30	$0.008per 100 RU/sec per hour	$576
Throughput bill for 3 additional regions - East US, North Europe, and East Asia	3 * 10K RU/sec * 24 * 30	$0.008per 100 RU/sec per hour	$1,728
Storage bill for container in West US	250 GB	$0.25/GB	$62.50
Storage bill for 3 additional regions - East US, North Europe, and East Asia	3 * 250 GB	$0.25/GB	$187.50

ITEM	USAGE (MONTH)	RATE	MONTHLY COST
Total			**$2,554**

Let's also assume that you egress 100 GB of data every month from the container in West US to replicate data into East US, North Europe, and East Asia. You're billed for egress as per data transfer rates.

Billing example: multi-region Azure Cosmos account, multi region writes

Let's assume you create an Azure Cosmos container in West US. The container is created with throughput 10K RU/sec and you store 1 TB of data this month. Let's assume you add three regions (East US, North Europe, and East Asia), each with the same storage and throughput and you want the ability to write to the containers in all regions associated with your Azure Cosmos account. Your total monthly bill will be (assuming 30 days in a month) as follows:

ITEM	USAGE (MONTH)	RATE	MONTHLY COST
Throughput bill for container in West US (all regions are writable)	10K RU/sec * 24 * 30	$0.016per 100 RU/sec per hour	$1,152
Throughput bill for 3 additional regions - East US, North Europe, and East Asia (all regions are writable)	(3 + 1) * 10K RU/sec * 24 * 30	$0.016per 100 RU/sec per hour	$4,608
Storage bill for container in West US	250 GB	$0.25/GB	$62.50
Storage bill for 3 additional regions - East US, North Europe, and East Asia	3 * 250 GB	$0.25/GB	$187.50
Total			**$6,010**

Let's also assume that you egress 100 GB of data every month from the container in West US to replicate data into East US, North Europe, and East Asia. You're billed for egress as per data transfer rates.

Billing example: Azure Cosmos account with multi-region writes, database-level throughput including dedicated throughput mode for some containers

Let's consider the following example, where we have a multi-region Azure Cosmos account where all regions are writable (multiple write regions config). For simplicity, we will assume storage size stays constant and doesn't change and omit it here to keep the example simpler. The provisioned throughput during the month varied as follows (assuming 30 days or 720 hours):

[0-100 hours]:

- We created a three region Azure Cosmos account (West US, East US, North Europe), where all regions are writable
- We created a database (D1) with shared throughput 10K RU/sec
- We created a database (D2) with shared throughput 30-K RU/sec and
- We created a container (C1) with dedicated throughput 20 K RU/sec

[101-200 hours]:

- We scaled up database (D1) to 50 K RU/sec
- We scaled up database (D2) to 70 K RU/sec
- We deleted container (C1)

[201-300 hours]:

- We created container (C1) again with dedicated throughput 20 K RU/sec

[301-400 hours]:

- We removed one of the regions from Azure Cosmos account (# of writable regions is now 2)
- We scaled down database (D1) to 10K RU/sec
- We scaled up database (D2) to 80 K RU/sec
- We deleted container (C1) again

[401-500 hours]:

- We scaled down database (D2) to 10K RU/sec
- We created container (C1) again with dedicated throughput 20 K RU/sec

[501-700 hours]:

- We scaled up database (D1) to 20 K RU/sec
- We scaled up database (D2) to 100 K RU/sec
- We deleted container (C1) again

[701-720 hours]:

- We scaled down database (D2) to 50 K RU/sec

Visually the changes in total provisioned throughput during 720 hours for the month are shown in the figure below:

The total monthly bill will be (assuming 30 days/720 hours in a month) will be computed as follows:

HOURS	RU/S	ITEM	USAGE (HOURLY)	COST

[0-100]	D1:10K
	D2:30K
	C1:20K
		Throughput bill for container in West US (all regions are writable)	`D1: 10K RU/sec/100 * $0.016 * 100 hours = $160`
			`D2: 30 K RU/sec/100 * $0.016 * 100 hours = $480`
			`C1: 20 K RU/sec/100 *$0.016 * 100 hours = $320`
				$960

		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(2 + 1) * (60 K RU/sec /100 * $0.016) * 100 hours = $2,880`	$2,880
[101-200]	D1:50K D2:70K C1: --	Throughput bill for container in West US (all regions are writable)	`D1: 50 K RU/sec/100 * $0.016 * 100 hours = $800` `D2: 70 K RU/sec/100 * $0.016 * 100 hours = $1,120`	$1920
		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(2 + 1) * (120 K RU/sec /100 * $0.016) * 100 hours = $5,760`	$5,760

[201-300]	D1:50K
	D2:70K
	C1:20K
		Throughput bill for container in West US (all regions are writable)	`D1: 50 K RU/sec/100 * $0.016 * 100 hours = $800`
			`D2: 70 K RU/sec/100 * $0.016 * 100 hours = $1,120`
			`C1: 20 K RU/sec/100 *$0.016 * 100 hours = $320`
				$2,240

		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(2 + 1) * (140 K RU/sec /100 * $0.016-) * 100 hours = $6,720`	$6,720
[301-400]	D1:10K D2:80K C1: --	Throughput bill for container in West US (all regions are writable)	`D1: 10K RU/sec/100 * $0.016 * 100 hours = $160` `D2: 80 K RU/sec/100 * $0.016 * 100 hours = $1,280`	$1,440

HOURS	RU/S	ITEM	USAGE (HOURLY)	COST
		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(1 + 1) * (90 K RU/sec /100 * $0.016) * 100 hours = $2,880`	$2,880

[401-500]	D1:10K
	D2:10K
	C1:20K
		Throughput bill for container in West US (all regions are writable)	`D1: 10K RU/sec/100 * $0.016 * 100 hours = $160`
			`D2: 10K RU/sec/100 * $0.016 * 100 hours = $160`
			`C1: 20 K RU/sec/100 *$0.016 * 100 hours = $320`
				$640

		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(1 + 1) * (40 K RU/sec /100 * $0.016) * 100 hours = $1,280`	$1,280
[501-700]	D1:20K D2:100K C1: --	Throughput bill for container in West US (all regions are writable)	`D1: 20 K RU/sec/100 * $0.016 * 200 hours = $640` `D2: 100 K RU/sec/100 * $0.016 * 200 hours = $3,200`	$3,840
		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(1 + 1) * (120 K RU/sec /100 * $0.016) * 200 hours = $1,280`	$7,680
[701-720]	D1:20K D2:50K C1: --	Throughput bill for container in West US (all regions are writable)	`D1: 20 K RU/sec/100 *$0.016 * 20 hours = $64` `D2: 50 K RU/sec/100 *$0.016 * 20 hours = $160`	$224
		Throughput bill for 2 additional regions: East US, North Europe (all regions are writable)	`(1 + 1) * (70 K RU/sec /100 * $0.016) * 20 hours = $448`	$224
		Total Monthly Cost		**$38,688**

Billing examples with free tier accounts

With Azure Cosmos DB free tier, you'll get the first 400 RU/s and 5 GB of storage in your account for free, applied at the account level. Any RU/s and storage beyond 400 RU/s and 5 GB will be billed at the regular pricing rates per the pricing page. On the bill, you will not see a charge or line item for the free 400 Ru/s and 5 GB, only the RU/s

and storage beyond what is covered by free tier. The 400 RU/s applies to any type of RU/s - provisioned throughput, autoscale, and multi-region writes.

Billing example - container or database with provisioned throughput

- Let's suppose we create a database or container in a free tier account with 400 RU/s and 5 GB of storage.
- Your bill will not show any charge for this resource. Your hourly and monthly cost will be $0.
- Now, let's suppose in the same account, we add another database or container with 1000 RU/s and 10 GB of storage.
- Your bill will now show a charge for the 1000 RU/s and 10 GB of storage.

Billing example - container with autoscale throughput

- Let's suppose in a free tier account, we create a container with autoscale enabled, with a maximum RU/s of 4000 RU/s. This resource will automatically scale between 400 RU/s - 4000 RU/s.
- Suppose in hour 1 through hour 10, the resource is at the minimum of 400 RU/s. During hour 11, the resource scales up to 1000 RU/s and then back down to 400 RU/s within the hour.
- In hours 1 through 10, you will be billed $0 for throughput, as the 400 RU/s were covered by free tier.
- In hour 11, you will be billed for an effective 1000 RU/s - 400 RU/s = 600 RU/s, as this is the highest RU/s in the hour. This will be 6 units of 100 RU/s for the hour, so the total throughput cost for the hour will be 6 units * $0.012 = $0.072.
- Any storage beyond the first 5 GB will be billed at normal storage rates.

Billing example - multi-region, single write region account

- Let's suppose in a free tier account, we create a database or container with 1200 RU/s and 10 GB of storage. We replicate the account to 3 regions, and we have a single write-region account.
- In total, without free tier, we would be billed for 3 * 1200 RU/s = 3600 RU/s and 3 * 10 GB = 30 GB of storage.
- With the free tier discount, after removing 400 RU/s and 5 GB of storage, we will be billed for an effective 3200 RU/s (32 units) of provisioned throughput at the single write region rate and 25 GB of storage.
- The monthly cost for RU/s would be: 32 units * $0.008 * 24 hours * 31 days = $190.46. The monthly cost for storage would be: 25 GB * 0.25 / GB = $6.25. The total cost would be $190.46 + $6.25 = $196.71.
- Note: if the unit price for RU/s or storage differs in the regions, the free tier 400 RU/s and 5 GB will reflect the rates of the region the account was created in.

Billing example - multi-region, account with multiple write regions

This example reflects pricing for multi-region writes for accounts created after December 1, 2019.

- Let's suppose in a free tier account, we create a database or container with 1200 RU/s and 10 GB of storage. We replicate the account to 3 regions, and we have a multiple write regions account.
- In total, without free tier, we would be billed for 3 * 1200 RU/s = 3600 RU/s and 3 * 10 GB = 30 GB of storage.
- With the free tier discount, after removing 400 RU/s and 5 GB of storage, we will be billed for an effective 3200 RU/s (32 units) of provisioned throughput at the multiple write region rate and 25 GB of storage.
- The monthly cost for RU/s would be: 32 units * $0.016 * 24 hours * 31 days = $380.93. The monthly cost for storage would be: 25 GB * 0.25 / GB = $6.25. The total cost would be $380.93 + $6.25 = $387.18.

Proactively estimating your monthly bill

Let's consider another example, where you want to proactively estimate your bill before the month's end. You can estimate your bill as follows:

Storage cost

- Avg Record Size (KB) = 1
- Number of Records = 100,000,000

- Total Storage (GB) = 100
- Monthly cost per GB = $0.25
- Expected Monthly Cost for Storage = $25.00

Throughput Cost

OPERATION TYPE	REQUESTS/SEC	AVG. RU/REQUEST	RUS NEEDED
Write	100	5	500
Read	400	1	400

Total RU/sec: 500 + 400 = 900 Hourly cost: 900/100 * $0.008 = $0.072 Expected Monthly Cost for Throughput (assuming 31 days): $0.072 * 24 * 31 = $53.57

Total Monthly Cost

Total Monthly Cost = Monthly Cost for Storage + Monthly Cost for Throughput Total Monthly Cost = $25.00 + $53.57 = $78.57

Pricing may vary by region. For up-to-date pricing, see the Pricing page.

Billing with Azure Cosmos DB reserved capacity

Azure Cosmos DB reserved capacity enables you to purchase provisioned throughput in advance (a reserved capacity or a reservation) that can be applied to all Azure Cosmos databases and containers (for any API or data model) across all Azure regions. Because provisioned throughput price varies per region, it helps to think of reserved capacity as a monetary credit that you've purchased at a discount, that can be drawn from for the provisioned throughput at the respective price in each region. For example, let's say you have an Azure Cosmos account with a single container provisioned with 50-K RU/sec and globally replicated two regions - East US and Japan East. If you choose the pay-as-you-go option, you would pay:

- in East US: for 50-K RU/sec at the rate of$0.008per 100 RU/sec in that region
- in Japan East: for 50-K RU/sec at the rate of$0.009per 100 RU/sec in that region

Your total bill (without reserved capacity) would be (assuming 30 days or 720 hours):

REGION	HOURLY PRICE PER 100 RU/S	UNITS (RU/S)	BILLED AMOUNT (HOURLY)	BILLED AMOUNT (MONTHLY)
East US	$0.008	50 K	$4	$2,880
Japan East	$0.009	50 K	$4.50	$3,240
Total			$8.50	$6,120

Let's consider that you've bought reserved capacity instead. You can buy reserved capacity for 100-K RU/sec at the price of$56,064 for one year (at 20% discount), or$6.40per hour. See reserved capacity pricing on the Pricing page).

- Cost of throughput (pay-as-you-go): 100,000 RU/sec/100 * $0.008/hour * 8760 hours in a year = $70,080
- Cost of throughput (with reserved capacity) $70,080 discounted at 20% = $56,064

What you've effectively purchased is a credit of$8per hour, for 100 K RU/sec using the list price in East US, at the price of$6.40per hour. You can then draw down from this pre-paid throughput reservation on an hourly basis for

the provisioned throughput capacity in any global Azure region at the respective regional list prices set for your subscription. In this example, where you provision 50 K RU/sec each in East US, and Japan East, you will be able to draw$8.00worth of provisioned throughput per hour, and will be billed the overage of$0.50per hour (or$360/month).

REGION	HOURLY PRICE PER 100 RU/S	UNITS (RU/S)	BILLED AMOUNT (HOURLY)	BILLED AMOUNT (MONTHLY)
East US	$0.008	50 K	$4	$2,880
Japan East	$0.009	50 K	$4.50	$3,240
		Pay-as-you-go	$8.50	$6120
Reserved Capacity Purchased	$0.0064 (20% discount)	100 RU/sec or $8 capacity pre-purchased	-$8	-$5,760
Net Bill			$0.50	$360

Optimize provisioned throughput cost in Azure Cosmos DB

12/4/2020 • 14 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

By offering provisioned throughput model, Azure Cosmos DB offers predictable performance at any scale. Reserving or provisioning throughput ahead of time eliminates the "noisy neighbor effect" on your performance. You specify the exact amount of throughput you need and Azure Cosmos DB guarantees the configured throughput, backed by SLA.

You can start with a minimum throughput of 400 RU/sec and scale up to tens of millions of requests per second or even more. Each request you issue against your Azure Cosmos container or database, such as a read request, write request, query request, stored procedures have a corresponding cost that is deducted from your provisioned throughput. If you provision 400 RU/s and issue a query that costs 40 RUs, you will be able to issue 10 such queries per second. Any request beyond that will get rate-limited and you should retry the request. If you are using client drivers, they support the automatic retry logic.

You can provision throughput on databases or containers and each strategy can help you save on costs depending on the scenario.

Optimize by provisioning throughput at different levels

- If you provision throughput on a database, all the containers, for example collections/tables/graphs within that database can share the throughput based on the load. Throughput reserved at the database level is shared unevenly, depending on the workload on a specific set of containers.
- If you provision throughput on a container, the throughput is guaranteed for that container, backed by the SLA. The choice of a logical partition key is crucial for even distribution of load across all the logical partitions of a container. See Partitioning and horizontal scaling articles for more details.

The following are some guidelines to decide on a provisioned throughput strategy:

Consider provisioning throughput on an Azure Cosmos database (containing a set of containers) if:

1. You have a few dozen Azure Cosmos containers and want to share throughput across some or all of them.
2. You are migrating from a single-tenant database designed to run on IaaS-hosted VMs or on-premises, for example, NoSQL or relational databases to Azure Cosmos DB. And if you have many collections/tables/graphs and you do not want to make any changes to your data model. Note, you might have to compromise some of the benefits offered by Azure Cosmos DB if you are not updating your data model when migrating from an on-premises database. It's recommended that you always reaccess your data model to get the most in terms of performance and also to optimize for costs.
3. You want to absorb unplanned spikes in workloads by virtue of pooled throughput at the database level subjected to unexpected spike in workload.
4. Instead of setting specific throughput on individual containers, you care about getting the aggregate throughput across a set of containers within the database.

Consider provisioning throughput on an individual container if:

1. You have a few Azure Cosmos containers. Because Azure Cosmos DB is schema-agnostic, a container can contain items that have heterogeneous schemas and does not require customers to create multiple container types, one for each entity. It is always an option to consider if grouping separate say 10-20 containers into a single container makes sense. With a 400 RUs minimum for containers, pooling all 10-20 containers into one could be more cost effective.

2. You want to control the throughput on a specific container and get the guaranteed throughput on a given container backed by SLA.

Consider a hybrid of the above two strategies:

1. As mentioned earlier, Azure Cosmos DB allows you to mix and match the above two strategies, so you can now have some containers within Azure Cosmos database, which may share the throughput provisioned on the database as well as, some containers within the same database, which may have dedicated amounts of provisioned throughput.

2. You can apply the above strategies to come up with a hybrid configuration, where you have both database level provisioned throughput with some containers having dedicated throughput.

As shown in the following table, depending on the choice of API, you can provision throughput at different granularities.

API	FOR SHARED THROUGHPUT, CONFIGURE	FOR DEDICATED THROUGHPUT, CONFIGURE
SQL API	Database	Container
Azure Cosmos DB's API for MongoDB	Database	Collection
Cassandra API	Keyspace	Table
Gremlin API	Database account	Graph
Table API	Database account	Table

By provisioning throughput at different levels, you can optimize your costs based on the characteristics of your workload. As mentioned earlier, you can programmatically and at any time increase or decrease your provisioned throughput for either individual container(s) or collectively across a set of containers. By elastically scaling throughput as your workload changes, you only pay for the throughput that you have configured. If your container or a set of containers is distributed across multiple regions, then the throughput you configure on the container or a set of containers is guaranteed to be made available across all regions.

Optimize with rate-limiting your requests

For workloads that aren't sensitive to latency, you can provision less throughput and let the application handle rate-limiting when the actual throughput exceeds the provisioned throughput. The server will preemptively end the request with `RequestRateTooLarge` (HTTP status code 429) and return the `x-ms-retry-after-ms` header indicating the amount of time, in milliseconds, that the user must wait before retrying the request.

```
HTTP Status 429,
 Status Line: RequestRateTooLarge
 x-ms-retry-after-ms :100
```

Retry logic in SDKs

The native SDKs (.NET/.NET Core, Java, Node.js and Python) implicitly catch this response, respect the server-

specified retry-after header, and retry the request. Unless your account is accessed concurrently by multiple clients, the next retry will succeed.

If you have more than one client cumulatively operating consistently above the request rate, the default retry count, which is currently set to 9, may not be sufficient. In such cases, the client throws a `RequestRateTooLargeException` with status code 429 to the application. The default retry count can be changed by setting the `RetryOptions` on the ConnectionPolicy instance. By default, the `RequestRateTooLargeException` with status code 429 is returned after a cumulative wait time of 30 seconds if the request continues to operate above the request rate. This occurs even when the current retry count is less than the max retry count, be it the default of 9 or a user-defined value.

MaxRetryAttemptsOnThrottledRequests is set to 3, so in this case, if a request operation is rate limited by exceeding the reserved throughput for the container, the request operation retries three times before throwing the exception to the application. MaxRetryWaitTimeInSeconds is set to 60, so in this case if the cumulative retry wait time in seconds since the first request exceeds 60 seconds, the exception is thrown.

```
ConnectionPolicy connectionPolicy = new ConnectionPolicy();
connectionPolicy.RetryOptions.MaxRetryAttemptsOnThrottledRequests = 3;
connectionPolicy.RetryOptions.MaxRetryWaitTimeInSeconds = 60;
```

Partitioning strategy and provisioned throughput costs

Good partitioning strategy is important to optimize costs in Azure Cosmos DB. Ensure that there is no skew of partitions, which are exposed through storage metrics. Ensure that there is no skew of throughput for a partition, which is exposed with throughput metrics. Ensure that there is no skew towards particular partition keys. Dominant keys in storage are exposed through metrics but the key will be dependent on your application access pattern. It's best to think about the right logical partition key. A good partition key is expected to have the following characteristics:

- Choose a partition key that spreads workload evenly across all partitions and evenly over time. In other words, you shouldn't have some keys to with majority of the data and some keys with less or no data.
- Choose a partition key that enables access patterns to be evenly spread across logical partitions. The workload is reasonably even across all the keys. In other words, the majority of the workload shouldn't be focused on a few specific keys.
- Choose a partition key that has a wide range of values.

The basic idea is to spread the data and the activity in your container across the set of logical partitions, so that resources for data storage and throughput can be distributed across the logical partitions. Candidates for partition keys may include the properties that appear frequently as a filter in your queries. Queries can be efficiently routed by including the partition key in the filter predicate. With such a partitioning strategy, optimizing provisioned throughput will be a lot easier.

Design smaller items for higher throughput

The request charge or the request processing cost of a given operation is directly correlated to the size of the item. Operations on large items will cost more than operations on smaller items.

Data access patterns

It is always a good practice to logically separate your data into logical categories based on how frequently you access the data. By categorizing it as hot, medium, or cold data you can fine-tune the storage consumed and the throughput required. Depending on the frequency of access, you can place the data into separate containers (for example, tables, graphs, and collections) and fine-tune the provisioned throughput on them to accommodate to the needs of that segment of data.

Furthermore, if you're using Azure Cosmos DB, and you know you are not going to search by certain data values or will rarely access them, you should store the compressed values of these attributes. With this method you save on storage space, index space, and provisioned throughput and result in lower costs.

Optimize by changing indexing policy

By default, Azure Cosmos DB automatically indexes every property of every record. This is intended to ease development and ensure excellent performance across many different types of ad hoc queries. If you have large records with thousands of properties, paying the throughput cost for indexing every property may not be useful, especially if you only query against 10 or 20 of those properties. As you get closer to getting a handle on your specific workload, our guidance is to tune your index policy. Full details on Azure Cosmos DB indexing policy can be found here.

Monitoring provisioned and consumed throughput

You can monitor the total number of RUs provisioned, number of rate-limited requests as well as the number of RUs you've consumed in the Azure portal. The following image shows an example usage metric:

You can also set alerts to check if the number of rate-limited requests exceeds a specific threshold. See How to monitor Azure Cosmos DB article for more details. These alerts can send an email to the account administrators or call a custom HTTP Webhook or an Azure Function to automatically increase provisioned throughput.

Scale your throughput elastically and on-demand

Since you are billed for the throughput provisioned, matching the provisioned throughput to your needs can help you avoid the charges for the unused throughput. You can scale your provisioned throughput up or down any time, as needed. If your throughput needs are very predictable you can use Azure Functions and use a Timer Trigger to increase or decrease throughput on a schedule.

- Monitoring the consumption of your RUs and the ratio of rate-limited requests may reveal that you do not need to keep provisioned throughout constant throughout the day or the week. You may receive less traffic at night or during the weekend. By using either Azure portal or Azure Cosmos DB native SDKs or REST API, you can scale your provisioned throughput at any time. Azure Cosmos DB's REST API provides endpoints to programmatically update the performance level of your containers making it straightforward to adjust the throughput from your code depending on the time of the day or the day of the week. The operation is performed without any downtime, and typically takes effect in less than a minute.

- One of the areas you should scale throughput is when you ingest data into Azure Cosmos DB, for example, during data migration. Once you have completed the migration, you can scale provisioned throughput down to handle the solution's steady state.
- Remember, the billing is at the granularity of one hour, so you will not save any money if you change your provisioned throughput more often than one hour at a time.

Determine the throughput needed for a new workload

To determine the provisioned throughput for a new workload, you can use the following steps:

1. Perform an initial, rough evaluation using the capacity planner and adjust your estimates with the help of the Azure Cosmos DB Explorer in the Azure portal.
2. It's recommended to create the containers with higher throughput than expected and then scaling down as needed.
3. It's recommended to use one of the native Azure Cosmos DB SDKs to benefit from automatic retries when requests get rate-limited. If you're working on a platform that is not supported and use Cosmos DB's REST API, implement your own retry policy using the `x-ms-retry-after-ms` header.
4. Make sure that your application code gracefully supports the case when all retries fail.
5. You can configure alerts from the Azure portalto get notifications for rate-limiting. You can start with conservative limits like 10 rate-limited requests over the last 15 minutes and switch to more eager rules once you figure out your actual consumption. Occasional rate-limits are fine, they show that you're playing with the limits you've set and that's exactly what you want to do.
6. Use monitoring to understand your traffic pattern, so you can consider the need to dynamically adjust your throughput provisioning over the day or a week.
7. Monitor your provisioned vs. consumed throughput ratio regularly to make sure you have not provisioned more than required number of containers and databases. Having a little over provisioned throughput is a good safety check.

Best practices to optimize provisioned throughput

The following steps help you to make your solutions highly scalable and cost-effective when using Azure Cosmos DB.

1. If you have significantly over provisioned throughput across containers and databases, you should review RUs provisioned Vs consumed RUs and fine-tune the workloads.
2. One method for estimating the amount of reserved throughput required by your application is to record the request unit RU charge associated with running typical operations against a representative Azure Cosmos container or database used by your application and then estimate the number of operations you anticipate to perform each second. Be sure to measure and include typical queries and their usage as well. To learn how to estimate RU costs of queries programmatically or using portal see Optimizing the cost of queries.
3. Another way to get operations and their costs in RUs is by enabling Azure Monitor logs, which will give you the breakdown of operation/duration and the request charge. Azure Cosmos DB provides request charge for every operation, so every operation charge can be stored back from the response and then used for analysis.
4. You can elastically scale up and down provisioned throughput as you need to accommodate your workload needs.
5. You can add and remove regions associated with your Azure Cosmos account as you need and control

costs.

6. Make sure you have even distribution of data and workloads across logical partitions of your containers. If you have uneven partition distribution, this may cause to provision higher amount of throughput than the value that is needed. If you identify that you have a skewed distribution, we recommend redistributing the workload evenly across the partitions or repartition the data.

7. If you have many containers and these containers do not require SLAs, you can use the database-based offer for the cases where the per container throughput SLAs do not apply. You should identify which of the Azure Cosmos containers you want to migrate to the database level throughput offer and then migrate them by using a change feed-based solution.

8. Consider using the "Cosmos DB Free Tier" (free for one year), Try Cosmos DB (up to three regions) or downloadable Cosmos DB emulator for dev/test scenarios. By using these options for test-dev, you can substantially lower your costs.

9. You can further perform workload-specific cost optimizations – for example, increasing batch-size, load-balancing reads across multiple regions, and de-duplicating data, if applicable.

10. With Azure Cosmos DB reserved capacity, you can get significant discounts for up to 65% for three years. Azure Cosmos DB reserved capacity model is an upfront commitment on requests units needed over time. The discounts are tiered such that the more request units you use over a longer period, the more your discount will be. These discounts are applied immediately. Any RUs used above your provisioned values are charged based on the non-reserved capacity cost. See Cosmos DB reserved capacity) for more details. Consider purchasing reserved capacity to further lower your provisioned throughput costs.

Optimize request cost in Azure Cosmos DB

11/2/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

This article describes how read and write requests translate into Request Units and how to optimize the cost of these requests. Read operations include point reads and queries. Write operations include insert, replace, delete, and upsert of items.

Azure Cosmos DB offers a rich set of database operations that operate on the items within a container. The cost associated with each of these operations varies based on the CPU, IO, and memory required to complete the operation. Instead of thinking about and managing hardware resources, you can think of a Request Unit (RU) as a single measure for the resources required to perform various database operations to serve a request.

Measuring the RU charge of a request

It is important to measure the RU charge of your requests to understand their actual cost and also evaluate the effectiveness of your optimizations. You can fetch this cost by using the Azure portal or inspecting the response sent back from Azure Cosmos DB through one of the SDKs. See Find the request unit charge in Azure Cosmos DB for detailed instructions on how to achieve that.

Reading data: point reads and queries

Read operations in Azure Cosmos DB are typically ordered from fastest/most efficient to slower/less efficient in terms of RU consumption as follows:

- Point reads (key/value lookup on a single item ID and partition key).
- Query with a filter clause within a single partition key.
- Query without an equality or range filter clause on any property.
- Query without filters.

Role of the consistency level

When using either the **strong** or **bounded staleness** consistency levels, the RU cost of any read operation (point read or query) is doubled.

Point reads

The only factor affecting the RU charge of a point read (besides the consistency level used) is the size of the item retrieved. The following table shows the RU cost of point reads for items that are 1 KB and 100 KB in size.

ITEM SIZE	COST OF ONE POINT READ
1 KB	1 RU
100 KB	10 RUs

Because point reads (key/value lookups on the item ID) are the most efficient kind of read, you should make sure your item ID has a meaningful value so you can fetch your items with a point read (instead of a query) when possible.

Queries

Request units for queries are dependent on a number of factors. For example, the number of Azure Cosmos items loaded/returned, the number of lookups against the index, the query compilation time etc. details. Azure Cosmos DB guarantees that the same query when executed on the same data will always consume the same number of request units even with repeat executions. The query profile using query execution metrics gives you a good idea of how the request units are spent.

In some cases you may see a sequence of 200 and 429 responses, and variable request units in a paged execution of queries, that is because queries will run as fast as possible based on the available RUs. You may see a query execution break into multiple pages/round trips between server and client. For example, 10,000 items may be returned as multiple pages, each charged based on the computation performed for that page. When you sum across these pages, you should get the same number of RUs as you would get for the entire query.

Metrics for troubleshooting queries

The performance and the throughput consumed by queries (including user-defined functions) mostly depend on the function body. The easiest way to find out how much time the query execution is spent in the UDF and the number of RUs consumed, is by enabling the query metrics. If you use the .NET SDK, here are sample query metrics returned by the SDK:

```
Retrieved Document Count : 1
Retrieved Document Size : 9,963 bytes
Output Document Count : 1
Output Document Size : 10,012 bytes
Index Utilization : 100.00 %
Total Query Execution Time : 0.48 milliseconds
 Query Preparation Times
 Query Compilation Time : 0.07 milliseconds
 Logical Plan Build Time : 0.03 milliseconds
 Physical Plan Build Time : 0.05 milliseconds
 Query Optimization Time : 0.00 milliseconds
 Index Lookup Time : 0.06 milliseconds
 Document Load Time : 0.03 milliseconds
 Runtime Execution Times
 Query Engine Execution Time : 0.03 milliseconds
 System Function Execution Time : 0.00 milliseconds
 User-defined Function Execution Time : 0.00 milliseconds
 Document Write Time : 0.00 milliseconds
 Client Side Metrics
 Retry Count : 1
Request Charge : 3.19 RUs
```

Best practices to cost optimize queries

Consider the following best practices when optimizing queries for cost:

- Colocate multiple entity types

  Try to colocate multiple entity types within a single or smaller number of containers. This method yields benefits not only from a pricing perspective, but also for query execution and transactions. Queries are scoped to a single container; and atomic transactions over multiple records via stored procedures/triggers are scoped to a partition key within a single container. Colocating entities within the same container can reduce the number of network round trips to resolve relationships across records. So it increases the end-to-end performance, enables atomic transactions over multiple records for a larger dataset, and as a result lowers costs. If colocating multiple entity types within a single or smaller number of containers is difficult for your scenario, usually because you are migrating an existing application and you do not want to make any code changes - you should then consider provisioning throughput at the database level.

- Measure and tune for lower request units/second usage

The complexity of a query impacts how many request units (RUs) are consumed for an operation. The number of predicates, nature of the predicates, number of UDFs, and the size of the source data set. All these factors influence the cost of query operations.

Azure Cosmos DB provides predictable performance in terms of throughput and latency by using a provisioned throughput model. The throughput provisioned is represented in terms of Request Units per second, or RU/s. A Request Unit (RU) is a logical abstraction over compute resources such as CPU, memory, IO, etc. that are required to perform a request. The provisioned throughput (RUs) is set aside and dedicated to your container or database to provide predictable throughput and latency. Provisioned throughput enables Azure Cosmos DB to provide predictable and consistent performance, guaranteed low latency, and high availability at any scale. Request units represent the normalized currency that simplifies the reasoning about how many resources an application needs.

Request charge returned in the request header indicates the cost of a given query. For example, if a query returns 1000 1-KB items, the cost of the operation is 1000. As such, within one second, the server honors only two such requests before rate limiting subsequent requests. For more information, see request units article and the request unit calculator.

Writing data

The RU cost of writing an item depends on:

- The item size.
- The number of properties covered by the indexing policy and needed to be indexed.

Inserting a 1 KB item with less than 5 properties to index costs around 5 RUs. Replacing an item costs two times the charge required to insert the same item.

Optimizing writes

The best way to optimize the RU cost of write operations is to rightsize your items and the number of properties that get indexed.

- Storing very large items in Azure Cosmos DB results in high RU charges and can be considered as an anti-pattern. In particular, don't store binary content or large chunks of text that you don't need to query on. A best practice is to put this kind of data in Azure Blob Storage and store a reference (or link) to the blob in the item you write to Azure Cosmos DB.
- Optimizing your indexing policy to only index the properties that your queries filter on can make a huge difference in the RUs consumed by your write operations. When creating a new container, the default indexing policy indexes each and every property found in your items. While this is a good default for development activities, it is highly recommended to re-evaluate and customize your indexing policy when going to production or when your workload begins to receive significant traffic.

When performing bulk ingestion of data, it is also recommended to use the Azure Cosmos DB bulk executor library as it is designed to optimize the RU consumption of such operations. Optionally, you can also use Azure Data Factory which is built on that same library.

Optimize storage cost in Azure Cosmos DB

11/2/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB offers unlimited storage and throughput. Unlike throughput, which you have to provision/configure on your Azure Cosmos containers or databases, the storage is billed based on a consumption basis. You are billed only for the logical storage you consume and you don't have to reserve any storage in advance. Storage automatically scales up and down based on the data that you add or remove to an Azure Cosmos container.

Storage cost

Storage is billed with the unit of GBs. Local SSD-backed storage is used by your data and indexing. The total storage used is equal to the storage required by the data and indexes used across all the regions where you are using Azure Cosmos DB. If you globally replicate an Azure Cosmos account across three regions, you will pay for the total storage cost in each of those three regions. To estimate your storage requirement, see capacity planner tool. The cost for storage in Azure Cosmos DB is $0.25 GB/month, see Pricing page for latest updates. You can set up alerts to determine storage used by your Azure Cosmos container, to monitor your storage, see Monitor Azure Cosmos DB) article.

Optimize cost with item size

Azure Cosmos DB expects the item size to be 2 MB or less for optimal performance and cost benefits. If you need any item to store larger than 2 MB of data, consider redesigning the item schema. In the rare event that you cannot redesign the schema, you can split the item into subitems and link them logically with a common identifier(ID). All the Azure Cosmos DB features work consistently by anchoring to that logical identifier.

Optimize cost with indexing

By default, the data is automatically indexed, which can increase the total storage consumed. However, you can apply custom index policies to reduce this overhead. Automatic indexing that has not been tuned through policy is about 10-20% of the item size. By removing or customizing index policies, you don't pay extra cost for writes and don't require additional throughput capacity. See Indexing in Azure Cosmos DB to configure custom indexing policies. If you have worked with relational databases before, you may think that "index everything" means doubling of storage or higher. However, in Azure Cosmos DB, in the median case, it's much lower. In Azure Cosmos DB, the storage overhead of index is typically low (10-20%) even with automatic indexing, because it is designed for a low storage footprint. By managing the indexing policy, you can control the tradeoff of index footprint and query performance in a more fine-grained manner.

Optimize cost with time to live and change feed

Once you no longer need the data you can gracefully delete it from your Azure Cosmos account by using time to live, change feed or you can migrate the old data to another data store such as Azure blob storage or Azure data warehouse. With time to live or TTL, Azure Cosmos DB provides the ability to delete items automatically from a container after a certain time period. By default, you can set time to live at the container level and override the value on a per-item basis. After you set the TTL at a container or at an item level, Azure Cosmos DB will automatically remove these items after the time period since the time they were last modified. By using change feed, you can migrate data to either another container in Azure Cosmos DB or to an external data store. The

migration takes zero down time and when you are done migrating, you can either delete or configure time to live to delete the source Azure Cosmos container.

Optimize cost with rich media data types

If you want to store rich media types, for example, videos, images, etc., you have a number of options in Azure Cosmos DB. One option is to store these rich media types as Azure Cosmos items. There is a 2-MB limit per item, and you can avoid this limit by chaining the data item into multiple subitems. Or you can store them in Azure Blob storage and use the metadata to reference them from your Azure Cosmos items. There are a number of pros and cons with this approach. The first approach gets you the best performance in terms of latency, throughput SLAs plus turnkey global distribution capabilities for the rich media data types in addition to your regular Azure Cosmos items. However the support is available at a higher price. By storing media in Azure Blob storage, you could lower your overall costs. If latency is critical, you could use premium storage for rich media files that are referenced from Azure Cosmos items. This integrates natively with CDN to serve images from the edge server at lower cost to circumvent geo-restriction. The down side with this scenario is that you have to deal with two services - Azure Cosmos DB and Azure Blob storage, which may increase operational costs.

Check storage consumed

To check the storage consumption of an Azure Cosmos container, you can run a HEAD or GET request on the container, and inspect the `x-ms-request-quota` and the `x-ms-request-usage` headers. Alternatively, when working with the .NET SDK, you can use the DocumentSizeQuota, and DocumentSizeUsage properties to get the storage consumed.

Using SDK

```
// Measure the item size usage (which includes the index size)
ResourceResponse<DocumentCollection> collectionInfo = await
client.ReadDocumentCollectionAsync(UriFactory.CreateDocumentCollectionUri("db", "coll"));

Console.WriteLine("Item size quota: {0}, usage: {1}", collectionInfo.DocumentQuota,
collectionInfo.DocumentUsage);
```

Optimize multi-region cost in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

You can add and remove regions to your Azure Cosmos account at any time. The throughput that you configure for various Azure Cosmos databases and containers is reserved in each region associated with your account. If the throughput provisioned per hour, that is the sum of RU/s configured across all the databases and containers for your Azure Cosmos account is `T` and the number of Azure regions associated with your database account is `N`, then the total provisioned throughput for your Cosmos account, for a given hour is equal to `T x N RU/s`.

Provisioned throughput with single write region costs $0.008/hour per 100 RU/s and provisioned throughput with multiple writable regions costs $0.016/per hour per 100 RU/s. To learn more, see Azure Cosmos DB Pricing page.

Costs for multiple write regions

In a multi-region writes system, the net available RUs for write operations increases `N` times where `N` is the number of write regions. Unlike single region writes, every region is now writable and supports conflict resolution. From the cost planning point of view, to perform `M` RU/s worth of writes worldwide, you will need to provision M `RUs` at a container or database level. You can then add as many regions as you would like and use them for writes to perform `M` RU worth of worldwide writes.

Example

Consider that you have a container in West US configured for single-region writes, provisioned with throughput of 10K RU/s, storing 0.5 TB of data this month. Let's assume you add a region, East US, with the same storage and throughput and you want the ability to write to the containers in both the regions from your app. Your new total monthly bill (assuming 730 hours in a month) will be as follows:

ITEM	USAGE (MONTHLY)	RATE	MONTHLY COST
Throughput bill for container in West US (single write region)	10K RU/s * 730 hours	$0.008per 100 RU/s per hour	$584
Throughput bill for container in 2 regions - West US & East US (multiple write regions)	2 * 10K RU/s * 730 hours	$0.016per 100 RU/s per hour	$2,336
Storage bill for container in West US	0.5 TB (or 512 GB)	$0.25/GB	$128
Storage bill for container in 2 regions - West US & East US	2 * 0.5 TB (or 1,024 GB)	$0.25/GB	$256

Improve throughput utilization on a per region-basis

If you have inefficient utilization, for example, one or more under-utilized read regions you can take steps to

make the maximum use of the RUs in read regions by using change feed from the read-region or move it to another secondary if over-utilized. You will need to ensure you optimize provisioned throughput (RUs) in the write region first. Writes cost more than reads unless very large queries so maintaining even utilization can be challenging. Overall, monitor the consumed throughput in your regions and add or remove regions on demand to scale your read and write throughput, making to sure understand the impact to latency for any apps that are deployed in the same region.

Optimize development and testing cost in Azure Cosmos DB

11/2/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

This article describes the different options to use Azure Cosmos DB for development and testing for free of cost, as well as techniques to optimize cost in development or test accounts.

Azure Cosmos DB emulator (locally downloadable version)

Azure Cosmos DB emulator is a local downloadable version that mimics the Azure Cosmos DB cloud service. You can write and test code that uses the Azure Cosmos DB APIs even if you have no network connection and without incurring any costs. Azure Cosmos DB emulator provides a local environment for development purposes with high fidelity to the cloud service. You can develop and test your application locally, without creating an Azure subscription. When you're ready to deploy your application to the cloud, update the connection string to connect to the Azure Cosmos DB endpoint in the cloud, no other modifications are needed. You can also set up a CI/CD pipeline with the Azure Cosmos DB emulator build task in Azure DevOps to run tests. You can get started by visiting the Azure Cosmos DB emulator article.

Azure Cosmos DB free tier

Azure Cosmos DB free tier makes it easy to get started, develop and test your applications, or even run small production workloads for free. When free tier is enabled on an account, you'll get the first 400 RU/s and 5 GB of storage in the account free. You can also create a shared throughput database with 25 containers that share 400 RU/s at the database level, all covered by free tier (limit 5 shared throughput databases in a free tier account). When using the free tier, if you provision a shared database with a minimum throughput of 400 RU/s, all the containers within that database can share the throughput. Any new databases with shared throughput or containers with dedicated throughput are billed at the regular pricing.

> **NOTE**
>
> Free tier is only available in provisioned throughput mode.

Free tier lasts indefinitely for the lifetime of the account and comes with all the benefits and features of a regular Azure Cosmos DB account, including unlimited storage and throughput (RU/s), SLAs, high availability, turnkey global distribution in all Azure regions, and more. You can have up to one free tier account per Azure subscription and must opt-in when creating the account. To get started, create a new account in Azure portal with free tier enabled or use an ARM Template. See the pricing page for more details.

Try Azure Cosmos DB for free

Try Azure Cosmos DB for free is a free of charge experience that allows you to experiment with Azure Cosmos DB in the cloud without signing up for an Azure account or using your credit card. The Try Azure Cosmos DB accounts are available for a limited time, currently 30 days. You can renew them at any time. Try Azure Cosmos DB accounts makes it easy to evaluate Azure Cosmos DB, build and test an application or use the Quickstarts or tutorials. You can also create a demo, perform unit testing, or even create a multi-region account and run an app

on it without incurring any costs. In a Try Azure Cosmos DB account, you can have one shared throughput database with a maximum of 25 containers and 20,000 RU/s of throughput, or one container with up to 5000 RU/s. To get started, see Try Azure Cosmos DB for free page.

Azure free account

Azure Cosmos DB is included in the Azure free account, which offers Azure credits and resources for free for a certain time period. Specifically for Azure Cosmos DB, this free account offers 5-GB storage and 400 RUs of provisioned throughput for the entire year. This experience enables any developer to easily test the features of Azure Cosmos DB or integrate it with other Azure services at zero cost. With Azure free account, you get a $200 credit to spend in the first 30 days. You won't be charged, even if you start using the services until you choose to upgrade. To get started, visit Azure free account page.

Azure Cosmos DB serverless

Azure Cosmos DB serverless lets you use your Azure Cosmos account in a consumption-based fashion where you are only charged for the Request Units consumed by your database operations and the storage consumed by your data. There is no minimum charge involved when using Azure Cosmos DB in serverless mode. Because it eliminates the concept of provisioned capacity, it is best suited for development or testing activities specifically when your database is idle most of the time.

Use shared throughput databases

In a shared throughput database, all containers inside the database share the provisioned throughput (RU/s) of the database. For example, if you provision a database with 400 RU/s and have four containers, all four containers will share the 400 RU/s. In a development or testing environment, where each container may be be accessed less frequently and thus require lower than the minimum of 400 RU/s, putting containers in a shared throughput database can help optimize cost.

For example, suppose your development or test account has four containers. If you create four containers with dedicated throughput (minimum of 400 RU/s), your total RU/s will be 1600 RU/s. In contrast, if you create a shared throughput database (minimum 400 RU/s) and put your containers there, your total RU/s will be just 400 RU/s. In general, shared throughput databases are great for scenarios where you don't need guaranteed throughput on any individual container. Learn more about shared throughput databases.

Optimize cost with reserved capacity in Azure Cosmos DB

11/2/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB reserved capacity helps you save money by committing to a reservation for Azure Cosmos DB resources for either one year or three years. With Azure Cosmos DB reserved capacity, you can get a discount on the throughput provisioned for Cosmos DB resources. Examples of resources are databases and containers (tables, collections, and graphs).

Azure Cosmos DB reserved capacity can significantly reduce your Cosmos DB costs—up to 65 percent on regular prices with a one-year or three-year upfront commitment. Reserved capacity provides a billing discount and doesn't affect the runtime state of your Azure Cosmos DB resources.

Azure Cosmos DB reserved capacity covers throughput provisioned for your resources. It doesn't cover the storage and networking charges. As soon as you buy a reservation, the throughput charges that match the reservation attributes are no longer charged at the pay-as-you go rates. For more information on reservations, see the Azure reservations article.

You can buy Azure Cosmos DB reserved capacity from the Azure portal. Pay for the reservation up front or with monthly payments. To buy reserved capacity:

- You must be in the Owner role for at least one Enterprise or individual subscription with pay-as-you-go rates.
- For Enterprise subscriptions, **Add Reserved Instances** must be enabled in the EA portal. Or, if that setting is disabled, you must be an EA Admin on the subscription.
- For the Cloud Solution Provider (CSP) program, only admin agents or sales agents can buy Azure Cosmos DB reserved capacity.

Determine the required throughput before purchase

The size of the reserved capacity purchase should be based on the total amount of throughput that the existing or soon-to-be-deployed Azure Cosmos DB resources will use on an hourly basis. For example: Purchase 30,000 RU/s reserved capacity if that's your consistent hourly usage pattern. In this example, any provisioned throughput above 30,000 RU/s will be billed using your Pay-as-you-go rate. If provisioned throughput is below 30,000 RU/s in an hour, then the extra reserved capacity for that hour will be wasted.

We calculate purchase recommendations based on your hourly usage pattern. Usage over last 7, 30 and 60 days is analyzed, and reserved capacity purchase that maximizes your savings is recommended. You can view recommended reservation sizes in the Azure portal using the following steps:

1. Sign in to the Azure portal.
2. Select **All services** > **Reservations** > **Add**.
3. From the **Purchase reservations** pane, choose **Azure Cosmos DB**.
4. Select the **Recommended** tab to view recommended reservations:

You can filter recommendations by the following attributes:

- **Term** (1 year or 3 years)

- **Billing frequency** (Monthly or Upfront)
- **Throughput Type** (RU/s vs multi-region write RU/s)

Additionally, you can scope recommendations to be within a single resource group, single subscription, or your entire Azure enrollment.

Here's an example recommendation:

This recommendation to purchase a 30,000 RU/s reservation indicates that, among 3 year reservations, a 30,000 RU/s reservation size will maximize savings. In this case, the recommendation is calculated based on the past 30 days of Azure Cosmos DB usage. If this customer expects that the past 30 days of Azure Cosmos DB usage is representative of future use, they would maximize savings by purchasing a 30,000 RU/s reservation.

Buy Azure Cosmos DB reserved capacity

1. Sign in to the Azure portal.
2. Select **All services** > **Reservations** > **Add**.
3. From the **Purchase reservations** pane, choose **Azure Cosmos DB** to buy a new reservation.
4. Fill in the required fields as described in the following table:

FIELD	DESCRIPTION
Scope	Option that controls how many subscriptions can use the billing benefit associated with the reservation. It also controls how the reservation is applied to specific subscriptions. If you select **Shared**, the reservation discount is applied to Azure Cosmos DB instances that run in any subscription within your billing context. The billing context is based on how you signed up for Azure. For enterprise customers, the shared scope is the enrollment and includes all subscriptions within the enrollment. For pay-as-you-go customers, the shared scope is all individual subscriptions with pay-as-you-go rates created by the account administrator. If you select **Single subscription**, the reservation discount is applied to Azure Cosmos DB instances in the selected subscription. If you select **Single resource group**, the reservation discount is applied to Azure Cosmos DB instances in the selected subscription and the selected resource group within that subscription. You can change the reservation scope after you buy the reserved capacity.

FIELD	DESCRIPTION
Subscription	Subscription that's used to pay for the Azure Cosmos DB reserved capacity. The payment method on the selected subscription is used in charging the costs. The subscription must be one of the following types: Enterprise Agreement (offer numbers: MS-AZR-0017P or MS-AZR-0148P): For an Enterprise subscription, the charges are deducted from the enrollment's monetary commitment balance or charged as overage. Individual subscription with pay-as-you-go rates (offer numbers: MS-AZR-0003P or MS-AZR-0023P): For an individual subscription with pay-as-you-go rates, the charges are billed to the credit card or invoice payment method on the subscription.
Resource Group	Resource group to which the reserved capacity discount is applied.
Term	One year or three years.
Throughput Type	Throughput is provisioned as request units. You can buy a reservation for the provisioned throughput for both setups - single region writes as well as multiple region writes. The throughput type has two values to choose from: 100 RU/s per hour and 100 multi-region writes RU/s per hour.
Reserved Capacity Units	The amount of throughput that you want to reserve. You can calculate this value by determining the throughput needed for all your Cosmos DB resources (for example, databases or containers) per region. You then multiply it by the number of regions that you'll associate with your Cosmos database. For example: If you have five regions with 1 million RU/sec in every region, select 5 million RU/sec for the reservation capacity purchase.

5. After you fill the form, the price required to purchase the reserved capacity is calculated. The output also shows the percentage of discount you get with the chosen options. Next click **Select**

6. In the **Purchase reservations** pane, review the discount and the price of the reservation. This reservation price applies to Azure Cosmos DB resources with throughput provisioned across all regions.

7. Select **Review + buy** and then **buy now**. You see the following page when the purchase is successful:

After you buy a reservation, it's applied immediately to any existing Azure Cosmos DB resources that match the terms of the reservation. If you don't have any existing Azure Cosmos DB resources, the reservation will apply when you deploy a new Cosmos DB instance that matches the terms of the reservation. In both cases, the period

of the reservation starts immediately after a successful purchase.

When your reservation expires, your Azure Cosmos DB instances continue to run and are billed at the regular pay-as-you-go rates.

Cancel, exchange, or refund reservations

You can cancel, exchange, or refund reservations with certain limitations. For more information, see Self-service exchanges and refunds for Azure Reservations.

Next steps

The reservation discount is applied automatically to the Azure Cosmos DB resources that match the reservation scope and attributes. You can update the scope of the reservation through the Azure portal, PowerShell, Azure CLI, or the API.

Change feed in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Change feed in Azure Cosmos DB is a persistent record of changes to a container in the order they occur. Change feed support in Azure Cosmos DB works by listening to an Azure Cosmos container for any changes. It then outputs the sorted list of documents that were changed in the order in which they were modified. The persisted changes can be processed asynchronously and incrementally, and the output can be distributed across one or more consumers for parallel processing.

Learn more about change feed design patterns.

Supported APIs and client SDKs

This feature is currently supported by the following Azure Cosmos DB APIs and client SDKs.

CLIENT DRIVERS	SQL API	AZURE COSMOS DB'S API FOR CASSANDRA	AZURE COSMOS DB'S API FOR MONGODB	GREMLIN API	TABLE API
.NET	Yes	Yes	Yes	Yes	No
Java	Yes	Yes	Yes	Yes	No
Python	Yes	Yes	Yes	Yes	No
Node/JS	Yes	Yes	Yes	Yes	No

Change feed and different operations

Today, you see all inserts and updates in the change feed. You can't filter the change feed for a specific type of operation. One possible alternative, is to add a "soft marker" on the item for updates and filter based on that when processing items in the change feed.

Currently change feed doesn't log deletes. Similar to the previous example, you can add a soft marker on the items that are being deleted. For example, you can add an attribute in the item called "deleted" and set it to "true" and set a TTL on the item, so that it can be automatically deleted. You can read the change feed for historic items (the most recent change corresponding to the item, it doesn't include the intermediate changes), for example, items that were added five years ago. You can read the change feed as far back as the origin of your container but if an item is deleted, it will be removed from the change feed.

Sort order of items in change feed

Change feed items come in the order of their modification time. This sort order is guaranteed per logical partition key.

Consistency level

While consuming the change feed in an Eventual consistency level, there could be duplicate events in-between subsequent change feed read operations (the last event of one read operation appears as the first of the next).

Change feed in multi-region Azure Cosmos accounts

In a multi-region Azure Cosmos account, if a write-region fails over, change feed will work across the manual failover operation and it will be contiguous.

Change feed and Time to Live (TTL)

If a TTL (Time to Live) property is set on an item to -1, change feed will persist forever. If the data is not deleted, it will remain in the change feed.

Change feed and _etag, _lsn or _ts

The _etag format is internal and you should not take dependency on it, because it can change anytime. _ts is a modification or a creation timestamp. You can use _ts for chronological comparison. _lsn is a batch ID that is added for change feed only; it represents the transaction ID. Many items may have same _lsn. ETag on FeedResponse is different from the _etag you see on the item. _etag is an internal identifier and it is used for concurrency control. The _etag property tells about the version of the item, whereas the ETag property is used for sequencing the feed.

Working with change feed

You can work with change feed using the following options:

- Using change feed with Azure Functions
- Using change feed with change feed processor

Change feed is available for each logical partition key within the container, and it can be distributed across one or more consumers for parallel processing as shown in the image below.

Features of change feed

- Change feed is enabled by default for all Azure Cosmos accounts.
- You can use your provisioned throughput to read from the change feed, just like any other Azure Cosmos DB operation, in any of the regions associated with your Azure Cosmos database.
- The change feed includes inserts and update operations made to items within the container. You can capture deletes by setting a "soft-delete" flag within your items (for example, documents) in place of deletes. Alternatively, you can set a finite expiration period for your items with the TTL capability. For example, 24 hours and use the value of that property to capture deletes. With this solution, you have to process the changes within a shorter time interval than the TTL expiration period.

- Each change to an item appears exactly once in the change feed, and the clients must manage the checkpointing logic. If you want to avoid the complexity of managing checkpoints, the change feed processor provides automatic checkpointing and "at least once" semantics. See using change feed with change feed processor.
- Only the most recent change for a given item is included in the change log. Intermediate changes may not be available.
- The change feed is sorted by the order of modification within each logical partition key value. There is no guaranteed order across the partition key values.
- Changes can be synchronized from any point-in-time, that is there is no fixed data retention period for which changes are available.
- Changes are available in parallel for all logical partition keys of an Azure Cosmos container. This capability allows changes from large containers to be processed in parallel by multiple consumers.
- Applications can request multiple change feeds on the same container simultaneously. ChangeFeedOptions.StartTime can be used to provide an initial starting point. For example, to find the continuation token corresponding to a given clock time. The ContinuationToken, if specified, takes precedence over the StartTime and StartFromBeginning values. The precision of ChangeFeedOptions.StartTime is ~5 secs.

Change feed in APIs for Cassandra and MongoDB

Change feed functionality is surfaced as change stream in MongoDB API and Query with predicate in Cassandra API. To learn more about the implementation details for MongoDB API, see the Change streams in the Azure Cosmos DB API for MongoDB.

Native Apache Cassandra provides change data capture (CDC), a mechanism to flag specific tables for archival as well as rejecting writes to those tables once a configurable size-on-disk for the CDC log is reached. The change feed feature in Azure Cosmos DB API for Cassandra enhances the ability to query the changes with predicate via CQL. To learn more about the implementation details, see Change feed in the Azure Cosmos DB API for Cassandra.

Built-in Jupyter Notebooks support in Azure Cosmos DB (preview)

11/2/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Jupyter Notebook is an open-source web application that allows you to create and share documents that contain live code, equations, visualizations, and narrative text.

Azure Cosmos DB built-in Jupyter Notebooks are directly integrated into the Azure portal and your Azure Cosmos DB accounts, making them convenient and easy to use. Developers, data scientists, engineers, and analysts can use the familiar Jupyter Notebooks experience to do data exploration, data cleaning, data transformations, numerical simulations, statistical modeling, data visualization, and machine learning.

Azure Cosmos DB supports both C# and Python notebooks for all APIs, including Core (SQL), Cassandra, Gremlin, Table, and API for MongoDB. Inside the notebook, you can take advantage of built-in commands and features that make it easy to create Azure Cosmos DB resources, upload data, and query and visualize your data in Azure Cosmos DB.

Benefits of Jupyter Notebooks

Jupyter Notebooks were originally developed for data science applications written in Python and R. However, they can be used in various ways for different kinds of projects, including:

Data visualization: Jupyter Notebooks allow you to visualize data in the form of a shared notebook that renders a data set as a graphic. You can create visualizations, make interactive changes to the shared code and data set, and share the results.

Code sharing: Services like GitHub provide ways to share code, but they're largely non-interactive. With a Jupyter Notebook, you can view code, execute it, and display the results directly in the Azure portal.

Live interactions with code: Code in a Jupyter Notebook is dynamic; you can edit it and run the updates incrementally in real time. You can also embed user controls (for example, sliders or text input fields) that are used as input sources for code, demos, or Proof of Concepts (POCs).

Documentation of code samples and outcomes of data exploration: If you have a piece of code and you want to explain line-by-line how it works, you can embed it in a Jupyter Notebook. You can add interactivity along with the documentation at the same time.

Built-in commands for Azure Cosmos DB: Azure Cosmos DB's built-in magic commands make it easy to interact with your account. You can use commands like %%upload and %%sql to upload data into a container and query it using SQL API syntax. You don't need to write additional custom code.

All in one place environment: Jupyter Notebooks combine code, rich text, images, videos, animations, mathematical equations, plots, maps, interactive figures, widgets, and graphical user interfaces into a single document.

Components of a Jupyter Notebook

Jupyter Notebooks can include several types of components, each organized into discrete blocks or cells:

Text and HTML: Plain text, or text annotated in the markdown syntax to generate HTML, can be inserted into the document at any point. CSS styling can also be included inline or added to the template used to generate the notebook.

Code and output: Jupyter Notebooks support Python and C# code. The results of the executed code appear

immediately after the code blocks, and the code blocks can be executed multiple times in any order you like.

Visualizations: You can generate graphics and charts from the code by using modules like Matplotlib, Plotly, Bokeh, and others. Similar to the output, these visualizations appear inline next to the code that generates them. Similar to the output, these visualizations appear inline next to the code that generates them.

Multimedia: Because Jupyter Notebooks are built on web technology, they can display all the types of multimedia supported by a web page. You can include them in a notebook as HTML elements, or you can generate them programmatically by using the `IPython.display` module.

Data: You can import the data from Azure Cosmos containers or the results of queries into a Jupyter Notebook programmatically. Use built-in magic commands to upload or query data in Azure Cosmos DB.

Next steps

To get started with built-in Jupyter Notebooks in Azure Cosmos DB, see the following articles:

- Enable notebooks in an Azure Cosmos account
- Use Python notebook features and commands
- Use C# notebook features and commands

Azure Cosmos DB service quotas

12/4/2020 • 11 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

This article provides an overview of the default quotas offered to different resources in the Azure Cosmos DB.

Storage and database operations

After you create an Azure Cosmos account under your subscription, you can manage data in your account by creating databases, containers, and items.

Provisioned throughput

You can provision throughput at a container-level or a database-level in terms of request units (RU/s or RUs). The following table lists the limits for storage and throughput per container/database.

RESOURCE	DEFAULT LIMIT
Maximum RUs per container (dedicated throughput provisioned mode)	1,000,000 by default. You can increase it by filing an Azure support ticket
Maximum RUs per database (shared throughput provisioned mode)	1,000,000 by default. You can increase it by filing an Azure support ticket
Maximum RUs per (logical) partition	10,000
Maximum storage across all items per (logical) partition	20 GB
Maximum number of distinct (logical) partition keys	Unlimited
Maximum storage per container	Unlimited
Maximum storage per database	Unlimited
Maximum attachment size per Account (Attachment feature is being deprecated)	2 GB
Minimum RU/s required per 1 GB	10 RU/s **Note:** if your container or database contains more than 1 TB of data, your account may be eligible to our "high storage / low throughput" program

> **NOTE**
>
> To learn about best practices for managing workloads that have partition keys requiring higher limits for storage or throughput, see Create a synthetic partition key.

Minimum throughput limits

A Cosmos container (or shared throughput database) must have a minimum throughput of 400 RU/s. As the

container grows, Cosmos DB requires a minimum throughput to ensure the database or container has sufficient resource for its operations.

The current and minimum throughput of a container or a database can be retrieved from the Azure portal or the SDKs. For more information, see Provision throughput on containers and databases.

The actual minimum RU/s may vary depending on your account configuration. You can use Azure Monitor metrics to view the history of provisioned throughput (RU/s) and storage on a resource.

Minimum throughput on container

To estimate the minimum throughput required of a container with manual throughput, find the maximum of:

- 400 RU/s
- Current storage in GB * 10 RU/s
- Highest RU/s provisioned on the container / 100

Example: Suppose you have a container provisioned with 400 RU/s and 0 GB storage. You increase the throughput to 50,000 RU/s and import 20 GB of data. The minimum RU/s is now `MAX(400, 20 * 10 RU/s per GB, 50,000 RU/s / 100)` = 500 RU/s. Over time, the storage grows to 200 GB. The minimum RU/s is now `MAX(400, 200 * 10 RU/s per GB, 50,000 / 100)` = 2000 RU/s.

Note: if your container or database contains more than 1 TB of data, your account may be eligible to our "high storage / low throughput" program.

Minimum throughput on shared throughput database

To estimate the minimum throughput required of a shared throughput database with manual throughput, find the maximum of:

- 400 RU/s
- Current storage in GB * 10 RU/s
- Highest RU/s provisioned on the database / 100
- 400 + MAX(Container count - 25, 0) * 100 RU/s

Example: Suppose you have a database provisioned with 400 RU/s, 15 GB of storage, and 10 containers. The minimum RU/s is `MAX(400, 15 * 10 RU/s per GB, 400 / 100, 400 + 0 )` = 400 RU/s. If there were 30 containers in the database, the minimum RU/s would be `400 + MAX(30 - 5, 0) * 100 RU/s` = 900 RU/s.

Note: if your container or database contains more than 1 TB of data, your account may be eligible to our "high storage / low throughput" program.

In summary, here are the minimum provisioned RU limits.

RESOURCE	DEFAULT LIMIT
Minimum RUs per container (dedicated throughput provisioned mode)	400
Minimum RUs per database (shared throughput provisioned mode)	400 RU/s for first 25 containers. Additional 100 RU/s for each container afterward.

Cosmos DB supports programmatic scaling of throughput (RU/s) per container or database via the SDKs or portal.

Depending on the current RU/s provisioned and resource settings, each resource can scale synchronously and immediately between the minimum RU/s to up to 100x the minimum RU/s. If the requested throughput value is outside the range, scaling is performed asynchronously. Asynchronous scaling may take minutes to hours to complete depending on the requested throughput and data storage size in the container.

Serverless

Serverless lets you use your Azure Cosmos DB resources in a consumption-based fashion. The following table lists the limits for storage and throughput burstability per container/database.

RESOURCE	LIMIT
Maximum RU/s per (logical) partition	5,000
Maximum storage across all items per (logical) partition	20 GB
Maximum number of distinct (logical) partition keys	Unlimited
Maximum storage per container	50 GB

Control plane operations

You can provision and manage your Azure Cosmos account using the Azure portal, Azure PowerShell, Azure CLI, and Azure Resource Manager templates. The following table lists the limits per subscription, account, and number of operations.

RESOURCE	DEFAULT LIMIT
Maximum database accounts per subscription	50 by default. You can increase it by filing an Azure support ticket
Maximum number of regional failovers	1/hour by default. You can increase it by filing an Azure support ticket

> **NOTE**
> Regional failovers only apply to single region writes accounts. Multi-region write accounts do not require or have any limits on changing the write region.

Cosmos DB automatically takes backups of your data at regular intervals. For details on backup retention intervals and windows, see Online backup and on-demand data restore in Azure Cosmos DB.

Per-account limits

Provisioned throughput

RESOURCE	DEFAULT LIMIT
Maximum number of databases	Unlimited
Maximum number of containers per database with shared throughput	25
Maximum number of containers per database or account with dedicated throughput	unlimited
Maximum number of regions	No limit (All Azure regions)

Serverless

RESOURCE	LIMIT
Maximum number of databases	Unlimited
Maximum number of containers per account	100
Maximum number of regions	1 (Any Azure region)

Per-container limits

Depending on which API you use, an Azure Cosmos container can represent either a collection, a table, or graph. Containers support configurations for unique key constraints, stored procedures, triggers, and UDFs, and indexing policy. The following table lists the limits specific to configurations within a container.

RESOURCE	DEFAULT LIMIT
Maximum length of database or container name	255
Maximum stored procedures per container	100 *
Maximum UDFs per container	25 *
Maximum number of paths in indexing policy	100 *
Maximum number of unique keys per container	10 *
Maximum number of paths per unique key constraint	16 *
Maximum TTL value	2147483647

* You can increase any of these per-container limits by creating an Azure Support request.

Per-item limits

Depending on which API you use, an Azure Cosmos item can represent either a document in a collection, a row in a table, or a node or edge in a graph. The following table shows the limits per item in Cosmos DB.

RESOURCE	DEFAULT LIMIT
Maximum size of an item	2 MB (UTF-8 length of JSON representation)
Maximum length of partition key value	2048 bytes
Maximum length of ID value	1023 bytes
Maximum number of properties per item	No practical limit
Maximum length of property name	No practical limit
Maximum length of property value	No practical limit
Maximum length of string property value	No practical limit

RESOURCE	DEFAULT LIMIT
Maximum length of numeric property value	IEEE754 double-precision 64-bit
Maximum level of nesting for embedded objects / arrays	128
Maximum TTL value	2147483647

There are no restrictions on the item payloads like number of properties and nesting depth, except for the length restrictions on partition key and ID values, and the overall size restriction of 2 MB. You may have to configure indexing policy for containers with large or complex item structures to reduce RU consumption. See Modeling items in Cosmos DB for a real-world example, and patterns to manage large items.

Per-request limits

Azure Cosmos DB supports CRUD and query operations against resources like containers, items, and databases. It also supports transactional batch requests against multiple items with the same partition key in a container.

RESOURCE	DEFAULT LIMIT
Maximum execution time for a single operation (like a stored procedure execution or a single query page retrieval)	5 sec
Maximum request size (for example, stored procedure, CRUD)	2 MB
Maximum response size (for example, paginated query)	4 MB
Maximum number of operations in a transactional batch	100

Once an operation like query reaches the execution timeout or response size limit, it returns a page of results and a continuation token to the client to resume execution. There is no practical limit on the duration a single query can run across pages/continuations.

Cosmos DB uses HMAC for authorization. You can use either a primary key, or a resource tokens for fine-grained access control to resources like containers, partition keys, or items. The following table lists limits for authorization tokens in Cosmos DB.

RESOURCE	DEFAULT LIMIT
Maximum primary token expiry time	15 min
Minimum resource token expiry time	10 min
Maximum resource token expiry time	24 h by default. You can increase it by filing an Azure support ticket
Maximum clock skew for token authorization	15 min

Cosmos DB supports execution of triggers during writes. The service supports a maximum of one pre-trigger and one post-trigger per write operation.

Metadata request limits

Azure Cosmos DB maintains system metadata for each account. This metadata allows you to enumerate

collections, databases, other Azure Cosmos DB resources, and their configurations for free of charge.

RESOURCE	DEFAULT LIMIT
Maximum collection create rate per minute	100
Maximum Database create rate per minute	100
Maximum provisioned throughput update rate per minute	5

Limits for autoscale provisioned throughput

See the Autoscale article and FAQ for more detailed explanation of the throughput and storage limits with autoscale.

RESOURCE	DEFAULT LIMIT
Maximum RU/s the system can scale to	`Tmax`, the autoscale max RU/s set by user
Minimum RU/s the system can scale to	`0.1 * Tmax`
Current RU/s the system is scaled to	`0.1*Tmax <= T <= Tmax`, based on usage
Minimum billable RU/s per hour	`0.1 * Tmax` Billing is done on a per-hour basis, where you are billed for the highest RU/s the system scaled to in the hour, or `0.1*Tmax`, whichever is higher.
Minimum autoscale max RU/s for a container	`MAX(4000, highest max RU/s ever provisioned / 10, current storage in GB * 100)` rounded to nearest 1000 RU/s
Minimum autoscale max RU/s for a database	`MAX(4000, highest max RU/s ever provisioned / 10, current storage in GB * 100, 4000 + (MAX(Container count - 25, 0) * 1000))` , rounded to nearest 1000 RU/s. Note if your database has more than 25 containers, the system increments the minimum autoscale max RU/s by 1000 RU/s per additional container. For example, if you have 30 containers, the lowest autoscale maximum RU/s you can set is 9000 RU/s (scales between 900 - 9000 RU/s).

SQL query limits

Cosmos DB supports querying items using SQL. The following table describes restrictions in query statements, for example in terms of number of clauses or query length.

RESOURCE	DEFAULT LIMIT
Maximum length of SQL query	256 KB
Maximum JOINs per query	5 *
Maximum UDFs per query	10 *

RESOURCE	DEFAULT LIMIT
Maximum points per polygon	4096
Maximum included paths per container	500
Maximum excluded paths per container	500
Maximum properties in a composite index	8

* You can increase any of these SQL query limits by creating an Azure Support request.

MongoDB API-specific limits

Cosmos DB supports the MongoDB wire protocol for applications written against MongoDB. You can find the supported commands and protocol versions at Supported MongoDB features and syntax.

The following table lists the limits specific to MongoDB feature support. Other service limits mentioned for the SQL (core) API also apply to the MongoDB API.

RESOURCE	DEFAULT LIMIT
Maximum MongoDB query memory size (This limitation is only for 3.2 server version)	40 MB
Maximum execution time for MongoDB operations	30s
Idle connection timeout for server side connection closure*	30 minutes

* We recommend that client applications set the idle connection timeout in the driver settings to 2-3 minutes because the default timeout for Azure LoadBalancer is 4 minutes. This timeout will ensure that idle connections are not closed by an intermediate load balancer between the client machine and Azure Cosmos DB.

Try Cosmos DB Free limits

The following table lists the limits for the Try Azure Cosmos DB for Free trial.

RESOURCE	DEFAULT LIMIT
Duration of the trial	30 days (a new trial can be requested after expiration) After expiration, the information stored is deleted.
Maximum containers per subscription (SQL, Gremlin, Table API)	1
Maximum containers per subscription (MongoDB API)	3
Maximum throughput per container	5000
Maximum throughput per shared-throughput database	20000
Maximum total storage per account	10 GB

Try Cosmos DB supports global distribution in only the Central US, North Europe, and Southeast Asia regions.

Azure support tickets can't be created for Try Azure Cosmos DB accounts. However, support is provided for subscribers with existing support plans.

Free tier account limits

The following table lists the limits for Azure Cosmos DB free tier accounts.

RESOURCE	DEFAULT LIMIT
Number of free tier accounts per Azure subscription	1
Duration of free-tier discount	Lifetime of the account. Must opt-in during account creation.
Maximum RU/s for free	400 RU/s
Maximum storage for free	5 GB
Maximum number of shared throughput databases	5
Maximum number of containers in a shared throughput database	25 In free tier accounts, the minimum RU/s for a shared throughput database with up to 25 containers is 400 RU/s.

In addition to the above, the Per-account limits also apply to free tier accounts.

Compliance in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

Azure Cosmos DB is available in all Azure regions. Microsoft makes five distinct Azure cloud environments available to customers:

- **Azure public** cloud, which is available globally.
- **Azure China 21Vianet** is available through a unique partnership between Microsoft and 21Vianet, one of the country/region's largest internet providers.
- **Azure Germany** provides services under a data trustee model, which ensures that customer data remains in Germany under the control of T-Systems International GmbH, a subsidiary of Deutsche Telecom, acting as the German data trustee.
- **Azure Government** is available in four regions in the United States to US government agencies and their partners.
- **Azure Government for Department of Defense(DoD)** is available in two regions in the United States to the US Department of Defense.

To help customers meet their own compliance obligations across regulated industries and markets worldwide, Azure maintains the largest compliance portfolio in the industry in terms of both breadth (total number of offerings) and depth (number of customer-facing services in assessment scope). Azure compliance offerings are grouped into four segments - globally applicable, US Government, industry specific, and region or country/region specific. Compliance offerings are based on various types of assurances, including formal certifications, attestations, validations, authorizations, and assessments produced by independent third-party auditing firms, as well as contractual amendments, self-assessments, and customer guidance documents produced by Microsoft.

Azure Cosmos DB certifications

Azure Cosmos DB is continually expanding its certification coverage. Currently, Azure Cosmos DB is certified with the following certificates:

GLOBALLY APPLICABLE	US GOVERNMENT	INDUSTRY SPECIFIC	REGION OR COUNTRY SPECIFIC
CSA STAR Certification	DoD SRG Level 2	HIPAA BAA	Australia IRAP
CSA STAR Attestation	FedRAMP Moderate	HITRUST	Germany C5
ISO 20000-1:2011	GxP (FDA 21 CFR Part 11)	PCI DSS	Singapore MTCS Level 3
ISO 22301:2012			Spain ENS High
ISO 27001:2013			
ISO 27017:2015			

GLOBALLY APPLICABLE	US GOVERNMENT	INDUSTRY SPECIFIC	REGION OR COUNTRY SPECIFIC
ISO 27018:2014			
ISO 9001:2015			
ISO 27701:2019			
SOC 1, 2, 3			

To learn more about each of these compliance offerings and how they benefit you, see Microsoft Azure Compliance offerings, Appendix A & B.

The following table lists the certifications supported by Azure Cosmos DB in Azure Government:

GLOBALLY APPLICABLE	US GOVERNMENT	INDUSTRY SPECIFIC
CSA STAR Certification	CJIS	HIPAA BAA
CSA STAR Attestation	DoD SRG Level 2	HITRUST
ISO 20000-1:2011	DoD SRG Level 4	PCI DSS
ISO 9001:2012	DoD SRG Level 5	
ISO 27001:2013	FedRAMP High	
ISO 9001:2015	IRS 1075	
ISO 27017:2014	NIST CSF	
ISO 27018:2015	NIST SP 800-171	
SOC 1, 2, 3

Automated recommendations for Azure Cosmos DB

11/2/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API Cassandra API Gremlin API Table API Azure Cosmos DB API for MongoDB

All the cloud services including Azure Cosmos DB get frequent updates with new features, capabilities, and improvements. It's important for your application to keep up with the latest performance and security updates. The Azure portal offers customized recommendations that enable you to maximize the performance of your application. The Azure Cosmos DB's advisory engine continuously analyzes the usage history of your Azure Cosmos DB resources and provides recommendations based on your workload patterns. These recommendations correspond to areas like partitioning, indexing, network, security etc. These customized recommendations help you to improve the performance of your application.

View recommendations

You can view recommendations for Azure Cosmos DB in the following ways:

- One way to view the recommendations is within the notifications tab. If there are new recommendations, you will see a message bar. Sign into your Azure portal and navigate to your Azure Cosmos account. Within your Azure Cosmos account, open the **Notifications** pane and then select the **Recommendations** tab. You can select the message and view recommendations.

- You can also find the recommendations through Azure Advisor in categorized by different buckets such as cost, security, reliability, performance, and operational excellence. You can select specific subscriptions and filter by the resource type, which is **Azure Cosmos DB accounts**. When you select a specific recommendation, it displays the actions you can take to benefit your workloads.

Not all recommendations shown in the Azure Cosmos DB pane are available in the Azure Advisor and vice versa. That's because based on the type of recommendation they fit in either the Azure Advisor pane, Azure Cosmos DB pane or both.

Currently Azure Cosmos DB supports recommendations on the following areas. Each of these recommendations includes a link to the relevant section of the documentation, so it's easy for you to take the next steps.

SDK usage recommendations

In this category, the advisor detects the usage of an old version of SDKs and recommends that you upgrade to a newer version to leverage the latest bug fixes and performance improvements. Currently the following SDK-specific recommendations are available:

NAME	DESCRIPTION
Old Spark connector	Detects the usage of old versions of the Spark connector and recommends upgrading.
Old .NET SDK	Detects the usage of old versions of the .NET SDK and recommends upgrading.
Old Java SDK	Detects the usage of old versions of the Java connector and recommends upgrading.

Indexing recommendations

In this category, the advisor detects the indexing mode, indexing policy, indexed paths and recommends changing if the current configuration impacts the query performance. Currently the following indexing-specific recommendations are available:

NAME	DESCRIPTION
Lazy indexing	Detects usage of lazy indexing mode and recommends using consistent indexing mode instead. The purpose of Azure Cosmos DB's lazy indexing mode is limited and can impact the freshness of query results in some situations so consistent indexing mode is recommended.
Composite indexing	Detects the accounts where queries could benefit from composite indexes and recommend using them. Composite indexes can dramatically improve the performance and throughput consumption of some queries.
Default indexing policy with many indexed paths	Detects containers running on default indexing with many indexed paths and recommends customizing the indexing policy.
ORDER BY queries with high RU/s charge	Detects containers issuing ORDER BY queries with high RU/s charge and recommends exploring composite indexes.
MongoDB 3.6 accounts with no index and high RU/s consumption	Detects Azure Cosmos DB's API for MongoDB with 3.6 version of containers issuing queries with high RU/s charge and recommends adding indexes.

Cost optimization recommendations

In this category, the advisor detects the RU/s usage and determines that you can optimize the price by making some changes to your resources or by leveraging a different pricing model. Currently the following cost optimization-specific recommendations are available:

NAME	DESCRIPTION
Reserved capacity	Detects your RU/s utilization and recommends reserved instances to users who can benefit from it.
Inactive containers	Detects the containers that haven't been used for more than 30 days and recommends reducing the throughput for such containers or deleting them.
New subscriptions with high throughput	Detects new subscriptions with accounts spending unusually high RU/s per day and provides them a notification. This notification is specifically to bring awareness to new customers that Azure Cosmos DB operates on provisioned throughput-based model and not consumption-based model.

Migration recommendations

In this category, the advisor detects that you are using legacy features recommends migrating so that you can leverage Azure Cosmos DB's massive scalability and other benefits. Currently the following migration-specific recommendations are available:

NAME	DESCRIPTION
Non-partitioned containers	Detects fixed-size containers that are approaching their max storage limit and recommends migrating them to partitioned containers.

Query usage recommendations

In this category, the advisor detects the query execution and identifies that the query performance can be tuned with some changes. Currently the following query usage recommendations are available:

NAME	DESCRIPTION
Queries with fixed page size	Detects queries issued with a fixed page size and recommends using -1 (no limit on the page size) instead of defining a specific value. This option reduces the number of network round trips required to retrieve all results.

Next steps

- Tuning query performance in Azure Cosmos DB
- Troubleshoot query issues when using Azure Cosmos DB

Quickstart: Create an Azure Cosmos account, database, container, and items from the Azure portal

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is Microsoft's globally distributed multi-model database service. You can use Azure Cosmos DB to quickly create and query key/value databases, document databases, and graph databases, all of which benefit from the global distribution and horizontal scale capabilities at the core of Azure Cosmos DB.

This quickstart demonstrates how to use the Azure portal to create an Azure Cosmos DB SQL API account, create a document database, and container, and add data to the container.

Prerequisites

An Azure subscription or free Azure Cosmos DB trial account

- If you don't have an Azure subscription, create a free account before you begin.
- You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

Create an Azure Cosmos DB account

Go to the Azure portal to create an Azure Cosmos DB account. Search for and select **Azure Cosmos DB**.

1. Select **Add**.
2. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-31 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API. Learn more about the SQL API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.

SETTING	VALUE	DESCRIPTION
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.
Geo-Redundancy	Enable or Disable	Enable or disable global distribution on your account by pairing your region with a pair region. You can add more regions to your account later.
Multi-region Writes	Enable or Disable	Multi-region writes capability allows you to take advantage of the provisioned throughput for your databases and containers across the globe.
Availability Zones	Enable or Disable	Availability Zones help you further improve availability and resiliency of your application.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

Microsoft Azure (Preview) | Search resources, services, and docs (G+/)

Home > New >

Create Azure Cosmos DB Account

Basics | Networking | Backup Policy | Encryption | Tags | Review + create

Azure Cosmos DB is a globally distributed, multi-model, fully managed database service. Try it for free, for 30 days with unlimited renewals. Go to production starting at $24/month per database, multiple containers included. Learn more

Project Details

Select the subscription to manage deployed resources and costs. Use resource groups like folders to organize and manage all your resources.

Subscription * : SubscriptionName

Resource Group * : (New) my-resource-group

Create new

Instance Details

Account Name * : Enter account name

API * : Core (SQL)

Notebooks (Preview) : On / Off

Location * : (US) West US

Capacity mode : Provisioned throughput / Serverless (Preview)

Learn more about capacity mode

With Azure Cosmos DB free tier, you will get 400 RU/s and 5 GB of storage for free in an account. You can enable free tier on up to one account per subscription. Estimated $[illegible]/month discount per account.

Apply Free Tier Discount : Apply / Do Not Apply

Account Type : Production / Non-Production

Geo-Redundancy : Enable / Disable

Multi-region Writes : Enable / Disable

Review + create | Previous | Next: Networking

1. Select **Review + create**. You can skip the **Network** and **Tags** sections.
2. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

Subscription: Contoso Subscription
Resource group: myResourceGroup

DEPLOYMENT DETAILS (Download)

Start time: 3/21/2019, 5:00:03 PM
Duration: 5 minutes 38 seconds
Correlation ID: 8e0be948-0c60-4da0-0000-000000000000

RESOURCE	TYPE	STATUS	OPERATION DETAILS
mysqlapicosmosdb	Microsoft.DocumentDb/databaseAcc...	OK	Operation details

3. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a database and a container

You can use the Data Explorer in the Azure portal to create a database and container.

1. Select **Data Explorer** from the left navigation on your Azure Cosmos DB account page, and then select **New Container**.

   You may need to scroll right to see the **Add Container** window.

2. In the **Add container** pane, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	ToDoList	Enter *ToDoList* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later. **Note**: This setting is not available when creating a new container in a serverless account.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

Don't add **Unique keys** for this example. Unique keys let you add a layer of data integrity to the database by ensuring the uniqueness of one or more values per partition key. For more information, see Unique keys in Azure Cosmos DB.

3. Select **OK**. The Data Explorer displays the new database and the container that you created.

Add data to your database

Add data to your new database using Data Explorer.

1. In **Data Explorer**, expand the **ToDoList** database, and expand the **Items** container. Next, select **Items**, and then select **New Item**.

2. Add the following structure to the document on the right side of the **Documents** pane:

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Select **Save**.

4. Select **New Document** again, and create and save another document with a unique `id`, and any other properties and values you want. Your documents can have any structure, because Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created

so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.

2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

If you wish to delete just the database and use the Azure Cosmos account in future, you can delete the database with the following steps:

- Got to your Azure Cosmos account.
- Open **Data Explorer**, right click on the database that you want to delete and select **Delete Database**.
- Enter the Database ID/database name to confirm the delete operation.

Next steps

In this quickstart, you learned how to create an Azure Cosmos DB account, create a database and container using the Data Explorer. You can now import additional data to your Azure Cosmos DB account.

Import data into Azure Cosmos DB

Quickstart: Create an Azure Cosmos DB and a container by using an ARM template

12/4/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is Microsoft's fast NoSQL database with open APIs for any scale. You can use Azure Cosmos DB to quickly create and query key/value databases, document databases, and graph databases. This quickstart focuses on the process of deploying an Azure Resource Manager template (ARM template) to create an Azure Cosmos database and a container within that database. You can later store data in this container.

An ARM template is a JavaScript Object Notation (JSON) file that defines the infrastructure and configuration for your project. The template uses declarative syntax. In declarative syntax, you describe your intended deployment without writing the sequence of programming commands to create the deployment.

If your environment meets the prerequisites and you're familiar with using ARM templates, select the **Deploy to Azure** button. The template will open in the Azure portal.

Deploy to Azure

Prerequisites

An Azure subscription or free Azure Cosmos DB trial account

- If you don't have an Azure subscription, create a free account before you begin.
- You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

Review the template

The template used in this quickstart is from Azure Quickstart Templates.

```
{
  "$schema": "https://schema.management.azure.com/schemas/2019-04-01/deploymentTemplate.json#",

            }
          },
          "options": { "throughput": "[parameters('throughput')]" }
        }
      }
    ]
  }
```

Three Azure resources are defined in the template:

- Microsoft.DocumentDB/databaseAccounts: Create an Azure Cosmos account.
- Microsoft.DocumentDB/databaseAccounts/sqlDatabases: Create an Azure Cosmos database.
- Microsoft.DocumentDB/databaseAccounts/sqlDatabases/containers: Create an Azure Cosmos container.

More Azure Cosmos DB template samples can be found in the quickstart template gallery.

Deploy the template

1. Select the following image to sign in to Azure and open a template. The template creates an Azure Cosmos account, a database, and a container.

   Deploy to Azure

2. Select or enter the following values.

Unless it is specified, use the default values to create the Azure Cosmos resources.

- **Subscription**: select an Azure subscription.
- **Resource group**: select **Create new**, enter a unique name for the resource group, and then click **OK**.
- **Location**: select a location. For example, **Central US**.
- **Account Name**: enter a name for the Azure Cosmos account. It must be globally unique.

- **Location**: enter a location where you want to create your Azure Cosmos account. The Azure Cosmos account can be in the same location as the resource group.
- **Primary Region**: The primary replica region for the Azure Cosmos account.
- **Secondary region**: The secondary replica region for the Azure Cosmos account.
- **Default Consistency Level**: The default consistency level for the Azure Cosmos account.
- **Max Staleness Prefix**: Max stale requests. Required for BoundedStaleness.
- **Max Interval in Seconds**: Max lag time. Required for BoundedStaleness.
- **Database Name**: The name of the Azure Cosmos database.
- **Container Name**: The name of the Azure Cosmos container.
- **Throughput**: The throughput for the container, minimum throughput value is 400 RU/s.
- **I agree to the terms and conditions state above**: Select.

3. Select **Purchase**. After the Azure Cosmos account has been deployed successfully, you get a notification:

The Azure portal is used to deploy the template. In addition to the Azure portal, you can also use the Azure PowerShell, Azure CLI, and REST API. To learn other deployment methods, see Deploy templates.

Validate the deployment

You can either use the Azure portal to check the Azure Cosmos account, the database, and the container or use the following Azure CLI or Azure PowerShell script to list the secret created.

- CLI
- PowerShell

```
echo "Enter your Azure Cosmos account name:" &&
read cosmosAccountName &&
echo "Enter the resource group where the Azure Cosmos account exists:" &&
read resourcegroupName &&
az cosmosdb show -g $resourcegroupName -n $cosmosAccountName
```

Clean up resources

If you plan to continue working with subsequent quickstarts and tutorials, you might want to leave these resources in place. When no longer needed, delete the resource group, which deletes the Azure Cosmos account and the related resources. To delete the resource group by using Azure CLI or Azure PowerShell:

- CLI
- PowerShell

```
echo "Enter the Resource Group name:" &&
read resourceGroupName &&
az group delete --name $resourceGroupName &&
echo "Press [ENTER] to continue ..."
```

Next steps

In this quickstart, you created an Azure Cosmos account, a database and a container by using an ARM template and validated the deployment. To learn more about Azure Cosmos DB and Azure Resource Manager, continue on to the articles below.

- Read an Overview of Azure Cosmos DB
- Learn more about Azure Resource Manager
- Get other Azure Cosmos DB Resource Manager templates

Quickstart: Build a console app using the .NET V4 SDK to manage Azure Cosmos DB SQL API account resources.

11/2/2020 • 13 minutes to read • Edit Online

APPLIES TO: SQL API

Get started with the Azure Cosmos DB SQL API client library for .NET. Follow the steps in this doc to install the .NET V4 (Azure.Cosmos) package, build an app, and try out the example code for basic CRUD operations on the data stored in Azure Cosmos DB.

Azure Cosmos DB is Microsoft's fast NoSQL database with open APIs for any scale. You can use Azure Cosmos DB to quickly create and query key/value, document, and graph databases. Use the Azure Cosmos DB SQL API client library for .NET to:

- Create an Azure Cosmos database and a container
- Add sample data to the container
- Query the data
- Delete the database

Library source code | Package (NuGet)

Prerequisites

- Azure subscription - create one for free or you can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments.
- NET Core 3 SDK. You can verify which version is available in your environment by running `dotnet --version`.

Setting up

This section walks you through creating an Azure Cosmos account and setting up a project that uses Azure Cosmos DB SQL API client library for .NET to manage resources. The example code described in this article creates a `FamilyDatabase` database and family members (each family member is an item) within that database. Each family member has properties such as `Id, FamilyName, FirstName, LastName, Parents, Children, Address,`. The `LastName` property is used as the partition key for the container.

Create an Azure Cosmos account

If you use the Try Azure Cosmos DB for free option to create an Azure Cosmos account, you must create an Azure Cosmos DB account of type **SQL API**. An Azure Cosmos DB test account is already created for you. You don't have to create the account explicitly, so you can skip this section and move to the next section.

If you have your own Azure subscription or created a subscription for free, you should create an Azure Cosmos account explicitly. The following code will create an Azure Cosmos account with session consistency. The account is replicated in `South Central US` and `North Central US`.

You can use Azure Cloud Shell to create the Azure Cosmos account. Azure Cloud Shell is an interactive, authenticated, browser-accessible shell for managing Azure resources. It provides the flexibility of choosing the shell experience that best suits the way you work, either Bash or PowerShell. For this quickstart, choose **Bash** mode. Azure Cloud Shell also requires a storage account, you can create one when prompted.

Select the **Try It** button next to the following code, choose **Bash** mode select **create a storage account** and login to Cloud Shell. Next copy and paste the following code to Azure Cloud Shell and run it. The Azure Cosmos account name must be globally unique, make sure to update the `mysqlapicosmosdb` value before you run the command.

```
# Set variables for the new SQL API account, database, and container
resourceGroupName='myResourceGroup'
location='southcentralus'

# The Azure Cosmos account name must be globally unique, make sure to update the `mysqlapicosmosdb` value
before you run the command
accountName='mysqlapicosmosdb'

# Create a resource group
az group create \
    --name $resourceGroupName \
    --location $location

# Create a SQL API Cosmos DB account with session consistency and multi-region writes enabled
az cosmosdb create \
    --resource-group $resourceGroupName \
    --name $accountName \
    --kind GlobalDocumentDB \
    --locations regionName="South Central US" failoverPriority=0 --locations regionName="North Central US"
failoverPriority=1 \
    --default-consistency-level "Session" \
    --enable-multiple-write-locations true
```

The creation of the Azure Cosmos account takes a while, once the operation is successful, you can see the confirmation output. After the command completes successfully, sign into the Azure portal and verify that the Azure Cosmos account with the specified name exists. You can close the Azure Cloud Shell window after the resource is created.

Create a new .NET app

Create a new .NET application in your preferred editor or IDE. Open the Windows command prompt or a Terminal window from your local computer. You will run all the commands in the next sections from the command prompt or terminal. Run the following dotnet new command to create a new app with the name `todo`. The --langVersion parameter sets the LangVersion property in the created project file.

```
dotnet new console –langVersion:8 -n todo
```

Change your directory to the newly created app folder. You can build the application with:

```
cd todo
dotnet build
```

The expected output from the build should look something like this:

```
  Restore completed in 100.37 ms for C:\Users\user1\Downloads\CosmosDB_Samples\todo\todo.csproj.
  todo -> C:\Users\user1\Downloads\CosmosDB_Samples\todo\bin\Debug\netcoreapp3.0\todo.dll

Build succeeded.
    0 Warning(s)
    0 Error(s)

Time Elapsed 00:00:34.17
```

Install the Azure Cosmos DB package

While still in the application directory, install the Azure Cosmos DB client library for .NET Core by using the dotnet add package command.

```
dotnet add package Azure.Cosmos --version 4.0.0-preview3
```

Copy your Azure Cosmos account credentials from the Azure portal

The sample application needs to authenticate to your Azure Cosmos account. To authenticate, you should pass the Azure Cosmos account credentials to the application. Get your Azure Cosmos account credentials by following these steps:

1. Sign in to the Azure portal.
2. Navigate to your Azure Cosmos account.
3. Open the **Keys** pane and copy the **URI** and **PRIMARY KEY** of your account. You will add the URI and keys values to an environment variable in the next step.

Object model

Before you start building the application, let's look into the hierarchy of resources in Azure Cosmos DB and the object model used to create and access these resources. The Azure Cosmos DB creates resources in the following order:

- Azure Cosmos account
- Databases
- Containers
- Items

To learn in more about the hierarchy of different entities, see the working with databases, containers, and items in Azure Cosmos DB article. You will use the following .NET classes to interact with these resources:

- CosmosClient - This class provides a client-side logical representation for the Azure Cosmos DB service. The client object is used to configure and execute requests against the service.
- CreateDatabaseIfNotExistsAsync - This method creates (if doesn't exist) or gets (if already exists) a database resource as an asynchronous operation.
- CreateContainerIfNotExistsAsync - This method creates (if it doesn't exist) or gets (if it already exists) a container as an asynchronous operation. You can check the status code from the response to determine whether the container was newly created (201) or an existing container was returned (200).
- CreateItemAsync - This method creates an item within the container.
- UpsertItemAsync - This method creates an item within the container if it doesn't already exist or replaces the item if it already exists.
- GetItemQueryIterator - This method creates a query for items under a container in an Azure Cosmos database using a SQL statement with parameterized values.

- DeleteAsync - Deletes the specified database from your Azure Cosmos account. `DeleteAsync` method only deletes the database.

Code examples

The sample code described in this article creates a family database in Azure Cosmos DB. The family database contains family details such as name, address, location, the associated parents, children, and pets. Before populating the data to your Azure Cosmos account, define the properties of a family item. Create a new class named `Family.cs` at the root level of your sample application and add the following code to it:

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace todo
{
    public class Family
    {
        [JsonPropertyName("id")]
        public string Id { get; set; }
        public string LastName { get; set; }
        public Parent[] Parents { get; set; }
        public Child[] Children { get; set; }
        public Address Address { get; set; }
        public bool IsRegistered { get; set; }
        public override string ToString()
        {
            return JsonSerializer.Serialize(this);
        }
    }

    public class Parent
    {
        public string FamilyName { get; set; }
        public string FirstName { get; set; }
    }

    public class Child
    {
        public string FamilyName { get; set; }
        public string FirstName { get; set; }
        public string Gender { get; set; }
        public int Grade { get; set; }
        public Pet[] Pets { get; set; }
    }

    public class Pet
    {
        public string GivenName { get; set; }
    }

    public class Address
    {
        public string State { get; set; }
        public string County { get; set; }
        public string City { get; set; }
    }
}
```

Add the using directives & define the client object

From the project directory, open the `Program.cs` file in your editor and add the following using directives at the top of your application:

```
using System;
using System.Collections.Generic;
using System.Net;
using System.Threading.Tasks;
using Azure.Cosmos;
```

Add the following global variables in your `Program` class. These will include the endpoint and authorization keys, the name of the database, and container that you will create. Make sure to replace the endpoint and authorization keys values according to your environment.

```
private const string EndpointUrl = "https://<your-account>.documents.azure.com:443/";
private const string AuthorizationKey = "<your-account-key>";
private const string DatabaseId = "FamilyDatabase";
private const string ContainerId = "FamilyContainer";
```

Finally, replace the `Main` method:

```
static async Task Main(string[] args)
{

    CosmosClient cosmosClient = new CosmosClient(EndpointUrl, AuthorizationKey);
    await Program.CreateDatabaseAsync(cosmosClient);
    await Program.CreateContainerAsync(cosmosClient);
    await Program.AddItemsToContainerAsync(cosmosClient);
    await Program.QueryItemsAsync(cosmosClient);
    await Program.ReplaceFamilyItemAsync(cosmosClient);
    await Program.DeleteFamilyItemAsync(cosmosClient);
    await Program.DeleteDatabaseAndCleanupAsync(cosmosClient);
}
```

Create a database

Define the `CreateDatabaseAsync` method within the `program.cs` class. This method creates the `FamilyDatabase` if it doesn't already exist.

```
/// <summary>
/// Create the database if it does not exist
/// </summary>
private static async Task CreateDatabaseAsync(CosmosClient cosmosClient)
{
    // Create a new database
    CosmosDatabase database = await cosmosClient.CreateDatabaseIfNotExistsAsync(Program.DatabaseId);
    Console.WriteLine("Created Database: {0}\n", database.Id);
}
```

Create a container

Define the `CreateContainerAsync` method within the `Program` class. This method creates the `FamilyContainer` if it doesn't already exist.

```
/// <summary>
/// Create the container if it does not exist.
/// Specify "/LastName" as the partition key since we're storing family information, to ensure good
distribution of requests and storage.
/// </summary>
/// <returns></returns>
private static async Task CreateContainerAsync(CosmosClient cosmosClient)
{
    // Create a new container
    CosmosContainer container = await
cosmosClient.GetDatabase(Program.DatabaseId).CreateContainerIfNotExistsAsync(Program.ContainerId,
"/LastName");
    Console.WriteLine("Created Container: {0}\n", container.Id);
}
```

Create an item

Create a family item by adding the `AddItemsToContainerAsync` method with the following code. You can use the `CreateItemAsync` or `UpsertItemAsync` methods to create an item:

```
/// <summary>
/// Add Family items to the container
/// </summary>
private static async Task AddItemsToContainerAsync(CosmosClient cosmosClient)
{
    // Create a family object for the Andersen family
    Family andersenFamily = new Family
    {
        Id = "Andersen.1",
        LastName = "Andersen",
        Parents = new Parent[]
        {
            new Parent { FirstName = "Thomas" },
            new Parent { FirstName = "Mary Kay" }
        },
        Children = new Child[]
        {
            new Child
            {
                FirstName = "Henriette Thaulow",
                Gender = "female",
                Grade = 5,
                Pets = new Pet[]
                {
                    new Pet { GivenName = "Fluffy" }
                }
            }
        },
        Address = new Address { State = "WA", County = "King", City = "Seattle" },
        IsRegistered = false
    };

    CosmosContainer container = cosmosClient.GetContainer(Program.DatabaseId, Program.ContainerId);
    try
    {
        // Read the item to see if it exists.
        ItemResponse<Family> andersenFamilyResponse = await container.ReadItemAsync<Family>(andersenFamily.Id,
new PartitionKey(andersenFamily.LastName));
        Console.WriteLine("Item in database with id: {0} already exists\n", andersenFamilyResponse.Value.Id);
    }
    catch(CosmosException ex) when (ex.Status == (int)HttpStatusCode.NotFound)
    {
        // Create an item in the container representing the Andersen family. Note we provide the value of the
partition key for this item, which is "Andersen"
        ItemResponse<Family> andersenFamilyResponse = await container.CreateItemAsync<Family>(andersenFamily,
new PartitionKey(andersenFamily.LastName));
```

```
        // Note that after creating the item, we can access the body of the item with the Resource property
off the ItemResponse.
        Console.WriteLine("Created item in database with id: {0}\n", andersenFamilyResponse.Value.Id);
    }

    // Create a family object for the Wakefield family
    Family wakefieldFamily = new Family
    {
        Id = "Wakefield.7",
        LastName = "Wakefield",
        Parents = new Parent[]
        {
            new Parent { FamilyName = "Wakefield", FirstName = "Robin" },
            new Parent { FamilyName = "Miller", FirstName = "Ben" }
        },
        Children = new Child[]
        {
            new Child
            {
                FamilyName = "Merriam",
                FirstName = "Jesse",
                Gender = "female",
                Grade = 8,
                Pets = new Pet[]
                {
                    new Pet { GivenName = "Goofy" },
                    new Pet { GivenName = "Shadow" }
                }
            },
            new Child
            {
                FamilyName = "Miller",
                FirstName = "Lisa",
                Gender = "female",
                Grade = 1
            }
        },
        Address = new Address { State = "NY", County = "Manhattan", City = "NY" },
        IsRegistered = true
    };

    // Create an item in the container representing the Wakefield family. Note we provide the value of the
partition key for this item, which is "Wakefield"
    ItemResponse<Family> wakefieldFamilyResponse = await container.UpsertItemAsync<Family>(wakefieldFamily,
new PartitionKey(wakefieldFamily.LastName));

    // Note that after creating the item, we can access the body of the item with the Resource property off
the ItemResponse. We can also access the RequestCharge property to see the amount of RUs consumed on this
request.
    Console.WriteLine("Created item in database with id: {0}\n", wakefieldFamilyResponse.Value.Id);
}
```

Query the items

After inserting an item, you can run a query to get the details of "Andersen" family. The following code shows how to execute the query using the SQL query directly. The SQL query to get the "Anderson" family details is: `SELECT * FROM c WHERE c.LastName = 'Andersen'`. Define the `QueryItemsAsync` method within the `Program` class and add the following code to it:

```
/// <summary>
/// Run a query (using Azure Cosmos DB SQL syntax) against the container
/// </summary>
private static async Task QueryItemsAsync(CosmosClient cosmosClient)
{
    var sqlQueryText = "SELECT * FROM c WHERE c.LastName = 'Andersen'";

    Console.WriteLine("Running query: {0}\n", sqlQueryText);

    CosmosContainer container = cosmosClient.GetContainer(Program.DatabaseId, Program.ContainerId);

    QueryDefinition queryDefinition = new QueryDefinition(sqlQueryText);

    List<Family> families = new List<Family>();

    await foreach (Family family in container.GetItemQueryIterator<Family>(queryDefinition))
    {
        families.Add(family);
        Console.WriteLine("\tRead {0}\n", family);
    }
}
```

Replace an item

Read a family item and then update it by adding the `ReplaceFamilyItemAsync` method with the following code.

```
/// <summary>
/// Replace an item in the container
/// </summary>
private static async Task ReplaceFamilyItemAsync(CosmosClient cosmosClient)
{
    CosmosContainer container = cosmosClient.GetContainer(Program.DatabaseId, Program.ContainerId);

    ItemResponse<Family> wakefieldFamilyResponse = await container.ReadItemAsync<Family>("Wakefield.7", new
PartitionKey("Wakefield"));
    Family itemBody = wakefieldFamilyResponse;

    // update registration status from false to true
    itemBody.IsRegistered = true;
    // update grade of child
    itemBody.Children[0].Grade = 6;

    // replace the item with the updated content
    wakefieldFamilyResponse = await container.ReplaceItemAsync<Family>(itemBody, itemBody.Id, new
PartitionKey(itemBody.LastName));
    Console.WriteLine("Updated Family [{0},{1}].\n \tBody is now: {2}\n", itemBody.LastName, itemBody.Id,
wakefieldFamilyResponse.Value);
}
```

Delete an item

Delete a family item by adding the `DeleteFamilyItemAsync` method with the following code.

```
/// <summary>
/// Delete an item in the container
/// </summary>
private static async Task DeleteFamilyItemAsync(CosmosClient cosmosClient)
{
    CosmosContainer container = cosmosClient.GetContainer(Program.DatabaseId, Program.ContainerId);

    string partitionKeyValue = "Wakefield";
    string familyId = "Wakefield.7";

    // Delete an item. Note we must provide the partition key value and id of the item to delete
    ItemResponse<Family> wakefieldFamilyResponse = await container.DeleteItemAsync<Family>(familyId,new
PartitionKey(partitionKeyValue));
    Console.WriteLine("Deleted Family [{0},{1}]\n", partitionKeyValue, familyId);
}
```

Delete the database

Finally you can delete the database adding the `DeleteDatabaseAndCleanupAsync` method with the following code:

```
/// <summary>
/// Delete the database and dispose of the Cosmos Client instance
/// </summary>
private static async Task DeleteDatabaseAndCleanupAsync(CosmosClient cosmosClient)
{
    CosmosDatabase database = cosmosClient.GetDatabase(Program.DatabaseId);
    DatabaseResponse databaseResourceResponse = await database.DeleteAsync();

    Console.WriteLine("Deleted Database: {0}\n", Program.DatabaseId);
}
```

After you add all the required methods, save the `Program` file.

Run the code

Next build and run the application to create the Azure Cosmos DB resources.

```
dotnet run
```

The following output is generated when you run the application. You can also sign into the Azure portal and validate that the resources are created:

```
Created Database: FamilyDatabase

Created Container: FamilyContainer

Created item in database with id: Andersen.1

Running query: SELECT * FROM c WHERE c.LastName = 'Andersen'

        Read {"id":"Andersen.1","LastName":"Andersen","Parents":[{"FamilyName":null,"FirstName":"Thomas"},
{"FamilyName":null   "FirstName":"Mary Kay"}],"Children":[{"FamilyName":null,"FirstName":"Henriette
Thaulow","Gender":"female","Grade":5,"Pets": [{"GivenName":"Fluffy"}]}],"Address":
{"State":"WA","County":"King","City":"Seattle"},"IsRegistered":false}

Updated Family [Wakefield,Wakefield.7].
        Body is now: {"id":"Wakefield.7","LastName":"Wakefield","Parents":
[{"FamilyName":"Wakefield","FirstName":"Robin"}   {"FamilyName":"Miller","FirstName":"Ben"}],"Children":
[{"FamilyName":"Merriam","FirstName":"Jesse","Gender":"female","Grade":6   "Pets":[{"GivenName":"Goofy"},
{"GivenName":"Shadow"}]},{"FamilyName":"Miller","FirstName":"Lisa","Gender":"female","Grade":1
"Pets":null}],"Address":{"State":"NY","County":"Manhattan","City":"NY"},"IsRegistered":true}

Deleted Family [Wakefield,Wakefield.7]

Deleted Database: FamilyDatabase

End of demo, press any key to exit.
```

You can validate that the data is created by signing into the Azure portal and see the required items in your Azure Cosmos account.

Clean up resources

When no longer needed, you can use the Azure CLI or Azure PowerShell to remove the Azure Cosmos account and the corresponding resource group. The following command shows how to delete the resource group by using the Azure CLI:

```
az group delete -g "myResourceGroup"
```

Next steps

In this quickstart, you learned how to create an Azure Cosmos account, create a database and a container using a .NET Core app. You can now import additional data to your Azure Cosmos account with the instructions int the following article.

Import data into Azure Cosmos DB

Quickstart: Build a .NET console app to manage Azure Cosmos DB SQL API resources

11/2/2020 • 12 minutes to read • Edit Online

APPLIES TO: SQL API

Get started with the Azure Cosmos DB SQL API client library for .NET. Follow the steps in this doc to install the .NET package, build an app, and try out the example code for basic CRUD operations on the data stored in Azure Cosmos DB.

Azure Cosmos DB is Microsoft's fast NoSQL database with open APIs for any scale. You can use Azure Cosmos DB to quickly create and query key/value, document, and graph databases. Use the Azure Cosmos DB SQL API client library for .NET to:

- Create an Azure Cosmos database and a container
- Add sample data to the container
- Query the data
- Delete the database

API reference documentation | Library source code | Package (NuGet)

Prerequisites

- Azure subscription - create one for free or you can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments.
- The .NET Core 2.1 SDK or later.

Setting up

This section walks you through creating an Azure Cosmos account and setting up a project that uses Azure Cosmos DB SQL API client library for .NET to manage resources. The example code described in this article creates a `FamilyDatabase` database and family members (each family member is an item) within that database. Each family member has properties such as `Id, FamilyName, FirstName, LastName, Parents, Children, Address,`. The `LastName` property is used as the partition key for the container.

Create an Azure Cosmos account

If you use the Try Azure Cosmos DB for free option to create an Azure Cosmos account, you must create an Azure Cosmos DB account of type **SQL API**. An Azure Cosmos DB test account is already created for you. You don't have to create the account explicitly, so you can skip this section and move to the next section.

If you have your own Azure subscription or created a subscription for free, you should create an Azure Cosmos account explicitly. The following code will create an Azure Cosmos account with session consistency. The account is replicated in `South Central US` and `North Central US`.

You can use Azure Cloud Shell to create the Azure Cosmos account. Azure Cloud Shell is an interactive, authenticated, browser-accessible shell for managing Azure resources. It provides the flexibility of choosing the shell experience that best suits the way you work, either Bash or PowerShell. For this quickstart, choose **Bash** mode. Azure Cloud Shell also requires a storage account, you can create one when prompted.

Select the **Try It** button next to the following code, choose **Bash** mode select **create a storage account** and login to Cloud Shell. Next copy and paste the following code to Azure Cloud Shell and run it. The Azure Cosmos

account name must be globally unique, make sure to update the `mysqlapicosmosdb` value before you run the command.

```
# Set variables for the new SQL API account, database, and container
resourceGroupName='myResourceGroup'
location='southcentralus'

# The Azure Cosmos account name must be globally unique, make sure to update the `mysqlapicosmosdb` value
before you run the command
accountName='mysqlapicosmosdb'

# Create a resource group
az group create \
    --name $resourceGroupName \
    --location $location

# Create a SQL API Cosmos DB account with session consistency and multi-region writes enabled
az cosmosdb create \
    --resource-group $resourceGroupName \
    --name $accountName \
    --kind GlobalDocumentDB \
    --locations regionName="South Central US" failoverPriority=0 --locations regionName="North Central US"
failoverPriority=1 \
    --default-consistency-level "Session" \
    --enable-multiple-write-locations true
```

The creation of the Azure Cosmos account takes a while, once the operation is successful, you can see the confirmation output. After the command completes successfully, sign into the Azure portal and verify that the Azure Cosmos account with the specified name exists. You can close the Azure Cloud Shell window after the resource is created.

Create a new .NET app

Create a new .NET application in your preferred editor or IDE. Open the Windows command prompt or a Terminal window from your local computer. You will run all the commands in the next sections from the command prompt or terminal. Run the following dotnet new command to create a new app with the name `todo`. The --langVersion parameter sets the LangVersion property in the created project file.

```
dotnet new console --langVersion 7.1 -n todo
```

Change your directory to the newly created app folder. You can build the application with:

```
cd todo
dotnet build
```

The expected output from the build should look something like this:

```
  Restore completed in 100.37 ms for C:\Users\user1\Downloads\CosmosDB_Samples\todo\todo.csproj.
  todo -> C:\Users\user1\Downloads\CosmosDB_Samples\todo\bin\Debug\netcoreapp2.2\todo.dll
  todo -> C:\Users\user1\Downloads\CosmosDB_Samples\todo\bin\Debug\netcoreapp2.2\todo.Views.dll

Build succeeded.
    0 Warning(s)
    0 Error(s)

Time Elapsed 00:00:34.17
```

Install the Azure Cosmos DB package

While still in the application directory, install the Azure Cosmos DB client library for .NET Core by using the dotnet add package command.

```
dotnet add package Microsoft.Azure.Cosmos
```

Copy your Azure Cosmos account credentials from the Azure portal

The sample application needs to authenticate to your Azure Cosmos account. To authenticate, you should pass the Azure Cosmos account credentials to the application. Get your Azure Cosmos account credentials by following these steps:

1. Sign in to the Azure portal.
2. Navigate to your Azure Cosmos account.
3. Open the **Keys** pane and copy the **URI** and **PRIMARY KEY** of your account. You will add the URI and keys values to an environment variable in the next step.

Set the environment variables

After you have copied the **URI** and **PRIMARY KEY** of your account, save them to a new environment variable on the local machine running the application. To set the environment variable, open a console window, and run the following command. Make sure to replace `<Your_Azure_Cosmos_account_URI>` and `<Your_Azure_Cosmos_account_PRIMARY_KEY>` values.

Windows

```
setx EndpointUrl "<Your_Azure_Cosmos_account_URI>"
setx PrimaryKey "<Your_Azure_Cosmos_account_PRIMARY_KEY>"
```

Linux

```
export EndpointUrl = "<Your_Azure_Cosmos_account_URI>"
export PrimaryKey = "<Your_Azure_Cosmos_account_PRIMARY_KEY>"
```

macOS

```
export EndpointUrl = "<Your_Azure_Cosmos_account_URI>"
export PrimaryKey = "<Your_Azure_Cosmos_account_PRIMARY_KEY>"
```

Object model

Before you start building the application, let's look into the hierarchy of resources in Azure Cosmos DB and the object model used to create and access these resources. The Azure Cosmos DB creates resources in the following order:

- Azure Cosmos account
- Databases
- Containers
- Items

To learn in more about the hierarchy of different entities, see the working with databases, containers, and items in Azure Cosmos DB article. You will use the following .NET classes to interact with these resources:

- CosmosClient - This class provides a client-side logical representation for the Azure Cosmos DB service. The client object is used to configure and execute requests against the service.
- CreateDatabaseIfNotExistsAsync - This method creates (if doesn't exist) or gets (if already exists) a database resource as an asynchronous operation.
- CreateContainerIfNotExistsAsync- - This method creates (if it doesn't exist) or gets (if it already exists) a container as an asynchronous operation. You can check the status code from the response to determine whether the container was newly created (201) or an existing container was returned (200).
- CreateItemAsync - This method creates an item within the container.
- UpsertItemAsync - This method creates an item within the container if it doesn't already exist or replaces the item if it already exists.
- GetItemQueryIterator - This method creates a query for items under a container in an Azure Cosmos database using a SQL statement with parameterized values.
- DeleteAsync - Deletes the specified database from your Azure Cosmos account. `DeleteAsync` method only deletes the database. Disposing of the `Cosmosclient` instance should happen separately (which it does in the DeleteDatabaseAndCleanupAsync method.

Code examples

The sample code described in this article creates a family database in Azure Cosmos DB. The family database contains family details such as name, address, location, the associated parents, children, and pets. Before populating the data to your Azure Cosmos account, define the properties of a family item. Create a new class named `Family.cs` at the root level of your sample application and add the following code to it:

```
using Newtonsoft.Json;

namespace todo
{
    public class Family
    {
        [JsonProperty(PropertyName = "id")]
        public string Id { get; set; }
        public string LastName { get; set; }
        public Parent[] Parents { get; set; }
        public Child[] Children { get; set; }
        public Address Address { get; set; }
        public bool IsRegistered { get; set; }
        // The ToString() method is used to format the output, it's used for demo purpose only. It's not
required by Azure Cosmos DB
        public override string ToString()
        {
            return JsonConvert.SerializeObject(this);
        }
    }

    public class Parent
    {
        public string FamilyName { get; set; }
        public string FirstName { get; set; }
    }

    public class Child
    {
        public string FamilyName { get; set; }
        public string FirstName { get; set; }
        public string Gender { get; set; }
        public int Grade { get; set; }
        public Pet[] Pets { get; set; }
    }

    public class Pet
    {
        public string GivenName { get; set; }
    }

    public class Address
    {
        public string State { get; set; }
        public string County { get; set; }
        public string City { get; set; }
    }
}
```

Add the using directives & define the client object

From the project directory, open the `Program.cs` file in your editor and add the following using directives at the top of your application:

```
using System;
using System.Threading.Tasks;
using System.Configuration;
using System.Collections.Generic;
using System.Net;
using Microsoft.Azure.Cosmos;
```

To the **Program.cs** file, add code to read the environment variables that you have set in the previous step. Define the `CosmosClient`, `Database`, and the `Container` objects. Next add code to the main method that calls the

`GetStartedDemoAsync` method where you manage Azure Cosmos account resources.

```
namespace todo
{
public class Program
{

    /// The Azure Cosmos DB endpoint for running this GetStarted sample.
    private string EndpointUrl = Environment.GetEnvironmentVariable("EndpointUrl");

    /// The primary key for the Azure DocumentDB account.
    private string PrimaryKey = Environment.GetEnvironmentVariable("PrimaryKey");

    // The Cosmos client instance
    private CosmosClient cosmosClient;

    // The database we will create
    private Database database;

    // The container we will create.
    private Container container;

    // The name of the database and container we will create
    private string databaseId = "FamilyDatabase";
    private string containerId = "FamilyContainer";

    public static async Task Main(string[] args)
    {
       try
       {
           Console.WriteLine("Beginning operations...\n");
           Program p = new Program();
           await p.GetStartedDemoAsync();

        }
        catch (CosmosException de)
        {
           Exception baseException = de.GetBaseException();
           Console.WriteLine("{0} error occurred: {1}", de.StatusCode, de);
        }
        catch (Exception e)
        {
            Console.WriteLine("Error: {0}", e);
        }
        finally
        {
            Console.WriteLine("End of demo, press any key to exit.");
            Console.ReadKey();
        }
    }
}
}
```

Create a database

Define the `CreateDatabaseAsync` method within the `program.cs` class. This method creates the `FamilyDatabase` if it doesn't already exist.

```
private async Task CreateDatabaseAsync()
{
    // Create a new database
    this.database = await this.cosmosClient.CreateDatabaseIfNotExistsAsync(databaseId);
    Console.WriteLine("Created Database: {0}\n", this.database.Id);
}
```

Create a container

Define the `CreateContainerAsync` method within the `program.cs` class. This method creates the `FamilyContainer` if it doesn't already exist.

```
/// Create the container if it does not exist.
/// Specifiy "/LastName" as the partition key since we're storing family information, to ensure good
distribution of requests and storage.
private async Task CreateContainerAsync()
{
    // Create a new container
    this.container = await this.database.CreateContainerIfNotExistsAsync(containerId, "/LastName");
    Console.WriteLine("Created Container: {0}\n", this.container.Id);
}
```

Create an item

Create a family item by adding the `AddItemsToContainerAsync` method with the following code. You can use the `CreateItemAsync` or `UpsertItemAsync` methods to create an item:

```
private async Task AddItemsToContainerAsync()
{
    // Create a family object for the Andersen family
    Family andersenFamily = new Family
    {
        Id = "Andersen.1",
        LastName = "Andersen",
        Parents = new Parent[]
        {
           new Parent { FirstName = "Thomas" },
           new Parent { FirstName = "Mary Kay" }
        },
        Children = new Child[]
        {
           new Child
            {
                FirstName = "Henriette Thaulow",
                Gender = "female",
                Grade = 5,
                Pets = new Pet[]
                {
                    new Pet { GivenName = "Fluffy" }
                }
            }
        },
        Address = new Address { State = "WA", County = "King", City = "Seattle" },
        IsRegistered = false
    };

    try
    {
        // Create an item in the container representing the Andersen family. Note we provide the value of
the partition key for this item, which is "Andersen".
        ItemResponse<Family> andersenFamilyResponse = await this.container.CreateItemAsync<Family>
(andersenFamily, new PartitionKey(andersenFamily.LastName));
        // Note that after creating the item, we can access the body of the item with the Resource property
of the ItemResponse. We can also access the RequestCharge property to see the amount of RUs consumed on this
request.
        Console.WriteLine("Created item in database with id: {0} Operation consumed {1} RUs.\n",
andersenFamilyResponse.Resource.Id, andersenFamilyResponse.RequestCharge);
    }
    catch (CosmosException ex) when (ex.StatusCode == HttpStatusCode.Conflict)
    {
        Console.WriteLine("Item in database with id: {0} already exists\n", andersenFamily.Id);
    }
}
```

Query the items

After inserting an item, you can run a query to get the details of "Andersen" family. The following code shows how to execute the query using the SQL query directly. The SQL query to get the "Anderson" family details is: `SELECT * FROM c WHERE c.LastName = 'Andersen'`. Define the `QueryItemsAsync` method within the `program.cs` class and add the following code to it:

```
private async Task QueryItemsAsync()
{
    var sqlQueryText = "SELECT * FROM c WHERE c.LastName = 'Andersen'";

    Console.WriteLine("Running query: {0}\n", sqlQueryText);

    QueryDefinition queryDefinition = new QueryDefinition(sqlQueryText);
    FeedIterator<Family> queryResultSetIterator = this.container.GetItemQueryIterator<Family>
(queryDefinition);

    List<Family> families = new List<Family>();

    while (queryResultSetIterator.HasMoreResults)
    {
        FeedResponse<Family> currentResultSet = await queryResultSetIterator.ReadNextAsync();
        foreach (Family family in currentResultSet)
        {
            families.Add(family);
            Console.WriteLine("\tRead {0}\n", family);
        }
    }
}
```

Delete the database

Finally you can delete the database adding the `DeleteDatabaseAndCleanupAsync` method with the following code:

```
private async Task DeleteDatabaseAndCleanupAsync()
{
   DatabaseResponse databaseResourceResponse = await this.database.DeleteAsync();
   // Also valid: await this.cosmosClient.Databases["FamilyDatabase"].DeleteAsync();

   Console.WriteLine("Deleted Database: {0}\n", this.databaseId);

   //Dispose of CosmosClient
    this.cosmosClient.Dispose();
}
```

Execute the CRUD operations

After you have defined all the required methods, execute them with in the `GetStartedDemoAsync` method. The `DeleteDatabaseAndCleanupAsync` method commented out in this code because you will not see any resources if that method is executed. You can uncomment it after validating that your Azure Cosmos DB resources were created in the Azure portal.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUrl, PrimaryKey);
    await this.CreateDatabaseAsync();
    await this.CreateContainerAsync();
    await this.AddItemsToContainerAsync();
    await this.QueryItemsAsync();
}
```

After you add all the required methods, save the `Program.cs` file.

Run the code

Next build and run the application to create the Azure Cosmos DB resources. Make sure to open a new

command prompt window, don't use the same instance that you have used to set the environment variables. Because the environment variables are not set in the current open window. You will need to open a new command prompt to see the updates.

```
dotnet build
```

```
dotnet run
```

The following output is generated when you run the application. You can also sign into the Azure portal and validate that the resources are created:

```
Created Database: FamilyDatabase

Created Container: FamilyContainer

Created item in database with id: Andersen.1 Operation consumed 11.62 RUs.

Running query: SELECT * FROM c WHERE c.LastName = 'Andersen'

        Read {"id":"Andersen.1","LastName":"Andersen","Parents":[{"FamilyName":null,"FirstName":"Thomas"},
{"FamilyName":null,"FirstName":"Mary Kay"}],"Children":[{"FamilyName":null,"FirstName":"Henriette
Thaulow","Gender":"female","Grade":5,"Pets":[{"GivenName":"Fluffy"}]}],"Address":
{"State":"WA","County":"King","City":"Seattle"},"IsRegistered":false}

End of demo, press any key to exit.
```

You can validate that the data is created by signing into the Azure portal and see the required items in your Azure Cosmos account.

Clean up resources

When no longer needed, you can use the Azure CLI or Azure PowerShell to remove the Azure Cosmos account and the corresponding resource group. The following command shows how to delete the resource group by using the Azure CLI:

```
az group delete -g "myResourceGroup"
```

Next steps

In this quickstart, you learned how to create an Azure Cosmos account, create a database and a container using a .NET Core app. You can now import additional data to your Azure Cosmos account with the instructions int the following article.

Import data into Azure Cosmos DB

Quickstart: Build a Java app to manage Azure Cosmos DB SQL API data

11/2/2020 • 15 minutes to read • Edit Online

APPLIES TO: SQL API

In this quickstart, you create and manage an Azure Cosmos DB SQL API account from the Azure portal, and by using a Java app cloned from GitHub. First, you create an Azure Cosmos DB SQL API account using the Azure portal, then create a Java app using the SQL Java SDK, and then add resources to your Cosmos DB account by using the Java application. Azure Cosmos DB is a multi-model database service that lets you quickly create and query document, table, key-value, and graph databases with global distribution and horizontal scale capabilities.

> **IMPORTANT**
>
> This quickstart is for Azure Cosmos DB Java SDK v4 only. Please view the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, Azure Cosmos DB Java SDK v4 performance tips, and Azure Cosmos DB Java SDK v4 troubleshooting guide for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

Prerequisites

- An Azure account with an active subscription. Create one for free. Or try Azure Cosmos DB for free without an Azure subscription. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081` and the key `C2y6yDjf5/R+ob0N8A7Cgv30VRDJIWEHLM+4QDU5DE2nQ9nDuVTqobD4b8mGGyPMbIZnqyMsEcaGQy67XIw/Jw==`.
- Java Development Kit (JDK) 8. Point your `JAVA_HOME` environment variable to the folder where the JDK is installed.
- A Maven binary archive. On Ubuntu, run `apt-get install maven` to install Maven.
- Git. On Ubuntu, run `sudo apt-get install git` to install Git.

Introductory notes

The structure of a Cosmos DB account. Irrespective of API or programming language, a Cosmos DB *account* contains zero or more *databases*, a *database* (DB) contains zero or more *containers*, and a *container* contains zero or more items, as shown in the diagram below:

You may read more about databases, containers and items here. A few important properties are defined at the level of the container, among them *provisioned throughput* and *partition key*.

The provisioned throughput is measured in Request Units (*RUs*) which have a monetary price and are a substantial determining factor in the operating cost of the account. Provisioned throughput can be selected at per-container granularity or per-database granularity, however container-level throughput specification is typically preferred. You may read more about throughput provisioning here.

As items are inserted into a Cosmos DB container, the database grows horizontally by adding more storage and compute to handle requests. Storage and compute capacity are added in discrete units known as *partitions*, and you must choose one field in your documents to be the partition key which maps each document to a partition. The way partitions are managed is that each partition is assigned a roughly equal slice out of the range of partition key values; therefore you are advised to choose a partition key which is relatively random or evenly-distributed. Otherwise, some partitions will see substantially more requests (*hot partition*) while other partitions see substantially fewer requests (*cold partition*), and this is to be avoided. You may learn more about partitioning here.

Create a database account

Before you can create a document database, you need to create a SQL API account with Azure Cosmos DB.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.

SETTING	VALUE	DESCRIPTION
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

> **NOTE**
>
> You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

> **NOTE**
>
> The following options are not available if you select **Serverless** as the **Capacity mode**:
>
> - Apply Free Tier Discount
> - Geo-redundancy
> - Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the uniqueness of one or

more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's switch to working with code. Let's clone a SQL API app from GitHub, set the connection string, and run it. You'll see how easy it is to work with data programmatically.

Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

```
git clone https://github.com/Azure-Samples/azure-cosmos-java-getting-started.git
```

Review the code

This step is optional. If you're interested in learning how the database resources are created in the code, you can review the following snippets. Otherwise, you can skip ahead to Run the app .

- Sync API
- Async API

Managing database resources using the synchronous (sync) API

- `CosmosClient` initialization. The `CosmosClient` provides client-side logical representation for the Azure Cosmos database service. This client is used to configure and execute requests against the service.

```
client = new CosmosClientBuilder()
    .endpoint(AccountSettings.HOST)
    .key(AccountSettings.MASTER_KEY)
    //  Setting the preferred location to Cosmos DB Account region
    //  West US is just an example. User should set preferred location to the Cosmos DB region closest
to the application
    .preferredRegions(Collections.singletonList("West US"))
    .consistencyLevel(ConsistencyLevel.EVENTUAL)
    .buildClient();
```

- `CosmosDatabase` creation.

```
CosmosDatabaseResponse cosmosDatabaseResponse = client.createDatabaseIfNotExists(databaseName);
database = client.getDatabase(cosmosDatabaseResponse.getProperties().getId());
```

- `CosmosContainer` creation.

```
CosmosContainerProperties containerProperties =
    new CosmosContainerProperties(containerName, "/lastName");

//  Create container with 400 RU/s
CosmosContainerResponse cosmosContainerResponse =
    database.createContainerIfNotExists(containerProperties,
ThroughputProperties.createManualThroughput(400));
container = database.getContainer(cosmosContainerResponse.getProperties().getId());
```

- Item creation by using the `createItem` method.

```
//  Create item using container that we created using sync client

//  Use lastName as partitionKey for cosmos item
//  Using appropriate partition key improves the performance of database operations
CosmosItemRequestOptions cosmosItemRequestOptions = new CosmosItemRequestOptions();
CosmosItemResponse<Family> item = container.createItem(family, new PartitionKey(family.getLastName()),
cosmosItemRequestOptions);
```

- Point reads are performed using `readItem` method.

```
try {
    CosmosItemResponse<Family> item = container.readItem(family.getId(), new
PartitionKey(family.getLastName()), Family.class);
    double requestCharge = item.getRequestCharge();
    Duration requestLatency = item.getDuration();
    logger.info("Item successfully read with id {} with a charge of {} and within duration {}",
        item.getItem().getId(), requestCharge, requestLatency);
} catch (CosmosException e) {
    logger.error("Read Item failed with", e);
}
```

- SQL queries over JSON are performed using the `queryItems` method.

```
// Set some common query options
CosmosQueryRequestOptions queryOptions = new CosmosQueryRequestOptions();
//queryOptions.setEnableCrossPartitionQuery(true); //No longer necessary in SDK v4
//  Set query metrics enabled to get metrics around query executions
queryOptions.setQueryMetricsEnabled(true);

CosmosPagedIterable<Family> familiesPagedIterable = container.queryItems(
    "SELECT * FROM Family WHERE Family.lastName IN ('Andersen', 'Wakefield', 'Johnson')", queryOptions,
Family.class);

familiesPagedIterable.iterableByPage(10).forEach(cosmosItemPropertiesFeedResponse -> {
    logger.info("Got a page of query result with {} items(s) and request charge of {}",
            cosmosItemPropertiesFeedResponse.getResults().size(),
cosmosItemPropertiesFeedResponse.getRequestCharge());

    logger.info("Item Ids {}", cosmosItemPropertiesFeedResponse
        .getResults()
        .stream()
        .map(Family::getId)
        .collect(Collectors.toList()));
});
```

Run the app

Now go back to the Azure portal to get your connection string information and launch the app with your endpoint information. This enables your app to communicate with your hosted database.

1. In the git terminal window, `cd` to the sample code folder.

   ```
   cd azure-cosmos-java-getting-started
   ```

2. In the git terminal window, use the following command to install the required Java packages.

   ```
   mvn package
   ```

3. In the git terminal window, use the following command to start the Java application (replace SYNCASYNCMODE with `sync` or `async` depending on which sample code you would like to run, replace YOUR_COSMOS_DB_HOSTNAME with the quoted URI value from the portal, and replace YOUR_COSMOS_DB_MASTER_KEY with the quoted primary key from portal)

   ```
   mvn exec:java@SYNCASYNCMODE -DACCOUNT_HOST=YOUR_COSMOS_DB_HOSTNAME -
   DACCOUNT_KEY=YOUR_COSMOS_DB_MASTER_KEY
   ```

   The terminal window displays a notification that the FamilyDB database was created.

4. The app creates database with name `AzureSampleFamilyDB`
5. The app creates container with name `FamilyContainer`
6. The app will perform point reads using object IDs and partition key value (which is lastName in our sample).
7. The app will query items to retrieve all families with last name in ('Andersen', 'Wakefield', 'Johnson')
8. The app doesn't delete the created resources. Switch back to the portal to clean up the resources. from your account so that you don't incur charges.

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.
2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on the charts.

3. Review the metrics on the other tabs.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.
2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos DB SQL API account, create a document database and container using the Data Explorer, and run a Java app to do the same thing programmatically. You can now import additional data into your Azure Cosmos DB account.

Import data into Azure Cosmos DB

Quickstart: Build a Spring Data Azure Cosmos DB v3 app to manage Azure Cosmos DB SQL API data

11/2/2020 • 11 minutes to read • Edit Online

APPLIES TO: SQL API

In this quickstart, you create and manage an Azure Cosmos DB SQL API account from the Azure portal, and by using a Spring Data Azure Cosmos DB v3 app cloned from GitHub. First, you create an Azure Cosmos DB SQL API account using the Azure portal, then create a Spring Boot app using the Spring Data Azure Cosmos DB v3 connector, and then add resources to your Cosmos DB account by using the Spring Boot application. Azure Cosmos DB is a multi-model database service that lets you quickly create and query document, table, key-value, and graph databases with global distribution and horizontal scale capabilities.

> **IMPORTANT**
>
> These release notes are for version 3 of Spring Data Azure Cosmos DB. You can find release notes for version 2 here.
>
> Spring Data Azure Cosmos DB supports only the SQL API.
>
> See these articles for information about Spring Data on other Azure Cosmos DB APIs:
>
> - Spring Data for Apache Cassandra with Azure Cosmos DB
> - Spring Data MongoDB with Azure Cosmos DB
> - Spring Data Gremlin with Azure Cosmos DB

Prerequisites

- An Azure account with an active subscription. Create one for free. Or try Azure Cosmos DB for free without an Azure subscription. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081` and the key `C2y6yDjf5/R+ob0N8A7Cgv30VRDJIWEHLM+4QDU5DE2nQ9nDuVTqobD4b8mGGyPMbIZnqyMsEcaGQy67XIw/Jw==`.
- Java Development Kit (JDK) 8. Point your `JAVA_HOME` environment variable to the folder where the JDK is installed.
- A Maven binary archive. On Ubuntu, run `apt-get install maven` to install Maven.
- Git. On Ubuntu, run `sudo apt-get install git` to install Git.

Introductory notes

The structure of a Cosmos DB account. Irrespective of API or programming language, a Cosmos DB *account* contains zero or more *databases*, a *database* (DB) contains zero or more *containers*, and a *container* contains zero or more items, as shown in the diagram below:

You may read more about databases, containers and items here. A few important properties are defined at the level of the container, among them *provisioned throughput* and *partition key*.

The provisioned throughput is measured in Request Units (*RUs*) which have a monetary price and are a substantial determining factor in the operating cost of the account. Provisioned throughput can be selected at per-container granularity or per-database granularity, however container-level throughput specification is typically preferred. You may read more about throughput provisioning here.

As items are inserted into a Cosmos DB container, the database grows horizontally by adding more storage and compute to handle requests. Storage and compute capacity are added in discrete units known as *partitions*, and you must choose one field in your documents to be the partition key which maps each document to a partition. The way partitions are managed is that each partition is assigned a roughly equal slice out of the range of partition key values; therefore you are advised to choose a partition key which is relatively random or evenly-distributed. Otherwise, some partitions will see substantially more requests (*hot partition*) while other partitions see substantially fewer requests (*cold partition*), and this is to be avoided. You may learn more about partitioning here.

Create a database account

Before you can create a document database, you need to create a SQL API account with Azure Cosmos DB.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.

SETTING	VALUE	DESCRIPTION
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the uniqueness of

one or more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's switch to working with code. Let's clone a SQL API app from GitHub, set the connection string, and run it. You'll see how easy it is to work with data programmatically.

Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

```
git clone https://github.com/Azure-Samples/azure-spring-data-cosmos-java-sql-api-getting-started.git
```

Review the code

This step is optional. If you're interested in learning how the database resources are created in the code, you can review the following snippets. Otherwise, you can skip ahead to Run the app .

Application configuration file

Here we showcase how Spring Boot and Spring Data enhance user experience - the process of establishing a Cosmos client and connecting to Cosmos resources is now config rather than code. At application startup Spring Boot handles all of this boilerplate using the settings in **application.properties**:

```
cosmos.uri=${ACCOUNT_HOST}
cosmos.key=${ACCOUNT_KEY}
cosmos.secondaryKey=${SECONDARY_ACCOUNT_KEY}

dynamic.collection.name=spel-property-collection
# Populate query metrics
cosmos.queryMetricsEnabled=true
```

Once you create an Azure Cosmos DB account, database, and container, just fill-in-the-blanks in the config file and Spring Boot/Spring Data will automatically do the following: (1) create an underlying Java SDK `CosmosClient` instance with the URI and key, and (2) connect to the database and container. You're all set - **no more resource management code!**

Java source

The Spring Data value-add also comes from its simple, clean, standardized and platform-independent interface for operating on datastores. Building on the Spring Data GitHub sample linked above, below are CRUD and query samples for manipulating Azure Cosmos DB documents with Spring Data Azure Cosmos DB.

- Item creation and updates by using the `save` method.

```
logger.info("Saving user : {}", testUser1);
userRepository.save(testUser1);
```

- Point-reads using the derived query method defined in the repository. The `findByIdAndLastName` performs point-reads for `UserRepository`. The fields mentioned in the method name cause Spring Data to execute a point-read defined by the `id` and `lastName` fields:

```
// to find by Id, please specify partition key value if collection is partitioned
final User result = userRepository.findByIdAndLastName(testUser1.getId(), testUser1.getLastName());
logger.info("Found user : {}", result);
```

- Item deletes using `deleteAll`:

```
userRepository.deleteAll();
```

- Derived query based on repository method name. Spring Data implements the `UserRepository` `findByFirstName` method as a Java SDK SQL query on the `firstName` field (this query could not be implemented as a point-read):

```
Flux<User> users = reactiveUserRepository.findByFirstName("testFirstName");
users.map(u -> {
    logger.info("user is : {}", u);
    return u;
}).subscribe();
```

Run the app

Now go back to the Azure portal to get your connection string information and launch the app with your endpoint information. This enables your app to communicate with your hosted database.

1. In the git terminal window, `cd` to the sample code folder.

```
cd azure-spring-data-cosmos-java-sql-api-getting-started/azure-spring-data-cosmos-java-getting-started/
```

2. In the git terminal window, use the following command to install the required Spring Data Azure Cosmos DB packages.

```
mvn clean package
```

3. In the git terminal window, use the following command to start the Spring Data Azure Cosmos DB application:

```
mvn spring-boot:run
```

4. The app loads **application.properties** and connects the resources in your Azure Cosmos DB account.
5. The app will perform point CRUD operations described above.
6. The app will perform a derived query.
7. The app doesn't delete your resources. Switch back to the portal to clean up the resources from your account if you want to avoid incurring charges.

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.
2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on the charts.

3. Review the metrics on the other tabs.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.

2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos DB SQL API account, create a document database and container using the Data Explorer, and run a Spring Data app to do the same thing programmatically. You can now import additional data into your Azure Cosmos DB account.

Import data into Azure Cosmos DB

Quickstart: Use Node.js to connect and query data from Azure Cosmos DB SQL API account

11/2/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

In this quickstart, you create and manage an Azure Cosmos DB SQL API account from the Azure portal, and by using a Node.js app cloned from GitHub. Azure Cosmos DB is a multi-model database service that lets you quickly create and query document, table, key-value, and graph databases with global distribution and horizontal scale capabilities.

Walkthrough video

Watch this video for a complete walkthrough of the content in this article.

Prerequisites

- An Azure account with an active subscription. Create one for free. Or try Azure Cosmos DB for free without an Azure subscription. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081` and the key `C2y6yDjf5/R+ob0N8A7Cgv30VRDJIWEHLM+4QDU5DE2nQ9nDuVTqobD4b8mGGyPMbIZnqyMsEcaGQy67XIw/Jw==`.
- Node.js 6.0.0+.
- Git.

Create an Azure Cosmos account

For this quickstart purpose, you can use the try Azure Cosmos DB for free option to create an Azure Cosmos account.

1. Navigate to the try Azure Cosmos DB for free page.
2. Choose the **SQL** API account and select **Create**. Sign-in using your Microsoft account.
3. After the sign-in is successful, your Azure Cosmos account should be ready. Select **Open in the Azure portal** to open the newly created account.

The "try Azure Cosmos DB for free" option doesn't require an Azure subscription and it offers you an Azure Cosmos account for a limited period of 30 days. If you want to use the Azure Cosmos account for a longer period, you should instead create the account within your Azure subscription.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the uniqueness of

one or more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's clone a Node.js app from GitHub, set the connection string, and run it.

1. Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

```
git clone https://github.com/Azure-Samples/azure-cosmos-db-sql-api-nodejs-getting-started.git
```

Review the code

This step is optional. If you're interested in learning how the Azure Cosmos database resources are created in the code, you can review the following snippets. Otherwise, you can skip ahead to Update your connection string.

If you're familiar with the previous version of the SQL JavaScript SDK, you may be used to seeing the terms *collection* and *document*. Because Azure Cosmos DB supports multiple API models, version 2.0+ of the JavaScript SDK uses the generic terms *container*, which may be a collection, graph, or table, and *item* to describe the content of the container.

The Cosmos DB JavaScript SDK is called "@azure/cosmos" and can be installed from npm...

```
npm install @azure/cosmos
```

The following snippets are all taken from the *app.js* file.

- The `CosmosClient` is imported from the `@azure/cosmos` npm package.

```
const CosmosClient = require("@azure/cosmos").CosmosClient;
```

- A new `CosmosClient` object is initialized.

```
const client = new CosmosClient({ endpoint, key });
```

- Select the "Tasks" database.

```
const database = client.database(databaseId);
```

- Select the "Items" container/collection.

```
const container = database.container(containerId);
```

- Select all the items in the "Items" container.

```
// query to return all items
const querySpec = {
  query: "SELECT * from c"
};

const { resources: items } = await container.items
  .query(querySpec)
  .fetchAll();
```

- Create a new item

```
const { resource: createdItem } = await container.items.create(newItem);
```

- Update an item

```
const { id, category } = createdItem;

createdItem.isComplete = true;
const { resource: updatedItem } = await container
  .item(id, category)
  .replace(createdItem);
```

- Delete an item

```
const { resource: result } = await container.item(id, category).delete();
```

> **NOTE**
> In both the "update" and "delete" methods, the item has to be selected from the database by calling `container.item()`. The two parameters passed in are the id of the item and the item's partition key. In this case, the parition key is the value of the "category" field.

Update your connection string

Now go back to the Azure portal to get the connection string details of your Azure Cosmos account. Copy the connection string into the app so that it can connect to your database.

1. In your Azure Cosmos DB account in the Azure portal, select **Keys** from the left navigation, and then select

Read-write Keys. Use the copy buttons on the right side of the screen to copy the URI and Primary Key into the *app.js* file in the next step.

2. In Open the *config.js* file.

3. Copy your URI value from the portal (using the copy button) and make it the value of the endpoint key in *config.js*.

```
endpoint: "<Your Azure Cosmos account URI>"
```

4. Then copy your PRIMARY KEY value from the portal and make it the value of the `config.key` in *config.js*. You've now updated your app with all the info it needs to communicate with Azure Cosmos DB.

```
key: "<Your Azure Cosmos account key>"
```

Run the app

1. Run `npm install` in a terminal to install the "@azure/cosmos" npm package

2. Run `node app.js` in a terminal to start your node application.

3. The two items that you created earlier in this quickstart are listed out. A new item is created. The "isComplete" flag on that item is updated to "true" and then finally, the item is deleted.

You can continue to experiment with this sample application or go back to Data Explorer, modify, and work with your data.

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.

2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on

the charts.

3. Review the metrics on the other tabs.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos DB account, create a container using the Data Explorer, and run a Node.js app. You can now import additional data to your Azure Cosmos DB account.

import data into azure cosmos db

Quickstart: Build a Python application using an Azure Cosmos DB SQL API account

11/2/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

In this quickstart, you create and manage an Azure Cosmos DB SQL API account from the Azure portal, and from Visual Studio Code with a Python app cloned from GitHub. Azure Cosmos DB is a multi-model database service that lets you quickly create and query document, table, key-value, and graph databases with global distribution and horizontal scale capabilities.

Prerequisites

- A Cosmos DB Account. You options are:
  - Within an Azure active subscription:
    - Create an Azure free Account or use your existing subscription
    - Visual Studio Monthly Credits
    - Azure Cosmos DB Free Tier
  - Without an Azure active subscription:
    - Try Azure Cosmos DB for free, a tests environment that lasts for 30 days.
    - Azure Cosmos DB Emulator
- Python 2.7 or 3.5.3+, with the `python` executable in your `PATH`.
- Visual Studio Code.
- The Python extension for Visual Studio Code.
- Git.
- Azure Cosmos DB SQL API SDK for Python

Create a database account

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.

SETTING	VALUE	DESCRIPTION
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the uniqueness of one or more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change

the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can

also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's clone a SQL API app from GitHub, set the connection string, and run it. This quickstart uses version 4 of the Python SDK.

1. Open a command prompt, create a new folder named git-samples, then close the command prompt.

   ```
   md "git-samples"
   ```

   If you are using a bash prompt, you should instead use the following command:

   ```
   mkdir "git-samples"
   ```

2. Open a git terminal window, such as git bash, and use the `cd` command to change to the new folder to install the sample app.

   ```
   cd "git-samples"
   ```

3. Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

   ```
   git clone https://github.com/Azure-Samples/azure-cosmos-db-python-getting-started.git
   ```

Update your connection string

Now go back to the Azure portal to get your connection string information and copy it into the app.

1. In your Azure Cosmos DB account in the Azure portal, select **Keys** from the left navigation. Use the copy buttons on the right side of the screen to copy the **URI** and **Primary Key** into the *cosmos_get_started.py* file in the next step.

2. In Visual Studio Code, open the *cosmos_get_started.py* file in *\git-samples\azure-cosmos-db-python-getting-started*.

3. Copy your **URI** value from the portal (using the copy button) and make it the value of the **endpoint** variable in *cosmos_get_started.py*.

```
endpoint = 'https://FILLME.documents.azure.com',
```

4. Then copy your **PRIMARY KEY** value from the portal and make it the value of the **key** in *cosmos_get_started.py*. You've now updated your app with all the info it needs to communicate with Azure Cosmos DB.

```
key = 'FILLME'
```

5. Save the *cosmos_get_started.py* file.

Review the code

This step is optional. Learn about the database resources created in code, or skip ahead to Update your connection string.

The following snippets are all taken from the *cosmos_get_started.py* file.

- The CosmosClient is initialized. Make sure to update the "endpoint" and "key" values as described in the Update your connection string section.

```
client = CosmosClient(endpoint, key)
```

- A new database is created.

```
database_name = 'AzureSampleFamilyDatabase'
database = client.create_database_if_not_exists(id=database_name)
```

- A new container is created, with 400 RU/s of provisioned throughput. We choose `lastName` as the partition key, which allows us to do efficient queries that filter on this property.

```
container_name = 'FamilyContainer'
container = database.create_container_if_not_exists(
    id=container_name,
    partition_key=PartitionKey(path="/lastName"),
    offer_throughput=400
)
```

- Some items are added to the container. Containers are a collection of items (JSON documents) that can have varied schema. The helper methods `get_[name]_family_item` return representations of a family that are stored in Azure Cosmos DB as JSON documents.

```
for family_item in family_items_to_create:
    container.create_item(body=family_item)
```

- Point reads (key value lookups) are performed using the `read_item` method. We print out the RU charge of each operation.

```
for family in family_items_to_create:
    item_response = container.read_item(item=family['id'], partition_key=family['lastName'])
    request_charge = container.client_connection.last_response_headers['x-ms-request-charge']
    print('Read item with id {0}. Operation consumed {1} request units'.format(item_response['id'],
(request_charge)))
```

- A query is performed using SQL query syntax. Because we're using partition key values of `lastName` in the WHERE clause, Azure Cosmos DB will efficiently route this query to the relevant partitions, improving performance.

```
query = "SELECT * FROM c WHERE c.lastName IN ('Wakefield', 'Andersen')"

items = list(container.query_items(
    query=query,
    enable_cross_partition_query=True
))

request_charge = container.client_connection.last_response_headers['x-ms-request-charge']

print('Query returned {0} items. Operation consumed {1} request units'.format(len(items),
request_charge))
```

Run the app

1. In Visual Studio Code, select **View** > **Command Palette**.
2. At the prompt, enter **Python: Select Interpreter** and then select the version of Python to use.

   The Footer in Visual Studio Code is updated to indicate the interpreter selected.
3. Select **View** > **Integrated Terminal** to open the Visual Studio Code integrated terminal.
4. In the integrated terminal window, ensure you are in the *azure-cosmos-db-python-getting-started* folder. If not, run the following command to switch to the sample folder.

```
cd "\git-samples\azure-cosmos-db-python-getting-started"`
```

5. Run the following command to install the azure-cosmos package.

```
pip install --pre azure-cosmos
```

If you get an error about access being denied when attempting to install azure-cosmos, you'll need to run VS Code as an administrator.

6. Run the following command to run the sample and create and store new documents in Azure Cosmos DB.

```
python cosmos_get_started.py
```

7. To confirm the new items were created and saved, in the Azure portal, select **Data Explorer** > **AzureSampleFamilyDatabase** > **Items**. View the items that were created. For example, here is a sample JSON document for the Andersen family:

```
{
    "id": "Andersen-1569479288379",
    "lastName": "Andersen",
    "district": "WA5",
    "parents": [
        {
            "familyName": null,
            "firstName": "Thomas"
        },
        {
            "familyName": null,
            "firstName": "Mary Kay"
        }
    ],
    "children": null,
    "address": {
        "state": "WA",
        "county": "King",
        "city": "Seattle"
    },
    "registered": true,
    "_rid": "8K5qAIYtZXeBhB4AAAAAAA==",
    "_self": "dbs/8K5qAA==/colls/8K5qAIYtZXc=/docs/8K5qAIYtZXeBhB4AAAAAAA==/",
    "_etag": "\"a3004d78-0000-0800-0000-5d8c5a780000\"",
    "_attachments": "attachments/",
    "_ts": 1569479288
}
```

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.

2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on the charts.

3. Review the metrics on the other tabs.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.

2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos DB account, create a container using the Data Explorer, and run a Python app in Visual Studio Code. You can now import additional data to your Azure Cosmos DB account.

Import data into Azure Cosmos DB for the SQL API

Quickstart: Build a todo app with Xamarin using Azure Cosmos DB SQL API account

11/2/2020 • 13 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is Microsoft's globally distributed multi-model database service. You can quickly create and query document, key/value, and graph databases, all of which benefit from the global distribution and horizontal scale capabilities at the core of Azure Cosmos DB.

> **NOTE**
> Sample code for an entire canonical sample Xamarin app showcasing multiple Azure offerings, including CosmosDB, can be found on GitHub here. This app demonstrates viewing geographically dispersed contacts, and allowing those contacts to update their location.

This quickstart demonstrates how to create an Azure Cosmos DB SQL API account, document database, and container using the Azure portal. You'll then build and deploy a todo list mobile app built on the SQL .NET API and Xamarin utilizing Xamarin.Forms and the MVVM architectural pattern.

Prerequisites

If you are developing on Windows and don't already have Visual Studio 2019 installed, you can download and use the **free** Visual Studio 2019 Community Edition. Make sure that you enable **Azure development** and **Mobile Development with .NET** workloads during the Visual Studio setup.

If you are using a Mac, you can download the **free** Visual Studio for Mac.

If you don't have an Azure subscription, create a free account before you begin.

You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

Create a database account

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.

SETTING	VALUE	DESCRIPTION
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the uniqueness of one or more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's clone the Xamarin SQL API app from GitHub, review the code, obtain the API keys, and run it. You'll see how easy it is to work with data programmatically.

1. Open a command prompt, create a new folder named git-samples, then close the command prompt.

```
mkdir "C:\git-samples"
```

2. Open a git terminal window, such as git bash, and use the `cd` command to change to the new folder to install the sample app.

```
cd "C:\git-samples"
```

3. Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

```
git clone https://github.com/Azure-Samples/azure-cosmos-db-sql-xamarin-getting-started.git
```

4. In Visual Studio, open **C:\git-samples\azure-cosmos-db-sql-xamarin-getting-started\src\ToDoItems.sln**

Obtain your API keys

Go back to the Azure portal to get your API key information and copy it into the app.

1. In the Azure portal, in your Azure Cosmos DB SQL API account, in the left navigation click **Keys**, and then click **Read-write Keys**. You'll use the copy buttons on the right side of the screen to copy the URI and Primary Key into the APIKeys.cs file in the next step.

2. In Visual Studio, open **ToDoItems.Core/Helpers/APIKeys.cs**.

3. In the Azure Portal, using the copy button, copy the **URI** value and make it the value of the `CosmosEndpointUrl` variable in APIKeys.cs.

```
//#error Enter the URL of your Azure Cosmos DB endpoint here
        public static readonly string CosmosEndpointUrl = "[URI Copied from Azure Portal]";
```

4. In the Azure Portal, using the copy button, copy the **PRIMARY KEY** value and make it the value of the `Cosmos Auth Key` in APIKeys.cs.

```
//#error Enter the read/write authentication key of your Azure Cosmos DB endpoint here
        public static readonly string CosmosAuthKey = "[PRIMARY KEY copied from Azure Portal";
```

> **IMPORTANT**
>
> This quick start hard codes the Azure Cosmos DB authentication key for the sake of demonstration purposes. It's not recommended to hard code an authentication key when you are using it in a production app. To learn how to access Azure Cosmos DB in a securely by using a resource token, view the Authenticating users with Azure Cosmos DB article.

Review the code

This solution demonstrates how to create a ToDo app using the Azure Cosmos DB SQL API and Xamarin.Forms. The app has two tabs, the first tab contains a list view showing todo items that are not yet complete. The second tab displays todo items that have been completed. In addition to viewing not completed todo items in the first tab, you can also add new todo items, edit existing ones, and mark items as completed.

The code in the ToDoItems solution contains:

- **ToDoItems.Core**
  - This is a .NET Standard project holding a Xamarin.Forms project and shared application logic code that maintains todo items within Azure Cosmos DB.
- **ToDoItems.Android**
  - This project contains the Android app.
- **ToDoItems.iOS**
  - This project contains the iOS app.

Now let's take a quick review of how the app communicates with Azure Cosmos DB.

- The Microsoft.Azure.DocumentDb.Core NuGet package is required to be added to all projects.
- The `ToDoItem` class in the **ToDoItems.Core/Models** folder models the documents in the **Items** container created above. Note that property naming is case-sensitive.
- The `CosmosDBService` class in the **ToDoItems.Core/Services** folder encapsulates the communication to Azure Cosmos DB.
- Within the `CosmosDBService` class there is a `DocumentClient` type variable. The `DocumentClient` is used to configure and execute requests against the Azure Cosmos DB account, and is instantiated:

  ```
  docClient = new DocumentClient(new Uri(APIKeys.CosmosEndpointUrl), APIKeys.CosmosAuthKey);
  ```

- When querying a container for documents, the `DocumentClient.CreateDocumentQuery<T>` method is used, as seen here in the `CosmosDBService.GetToDoItems` function:

```
/// <summary>
/// </summary>
/// <returns></returns>
public async static Task<List<ToDoItem>> GetToDoItems()
{
    var todos = new List<ToDoItem>();

    if (!await Initialize())
        return todos;

    var todoQuery = docClient.CreateDocumentQuery<ToDoItem>(
        UriFactory.CreateDocumentCollectionUri(databaseName, collectionName),
        new FeedOptions { MaxItemCount = -1, EnableCrossPartitionQuery = true })
        .Where(todo => todo.Completed == false)
        .AsDocumentQuery();

    while (todoQuery.HasMoreResults)
    {
        var queryResults = await todoQuery.ExecuteNextAsync<ToDoItem>();

        todos.AddRange(queryResults);
    }

    return todos;
}
```

The `CreateDocumentQuery<T>` takes a URI that points to the container created in the previous section. And you are also able to specify LINQ operators such as a `Where` clause. In this case only todo items that are not completed are returned.

The `CreateDocumentQuery<T>` function is executed synchronously, and returns an `IQueryable<T>`. However, the `AsDocumentQuery` method converts the `IQueryable<T>` to an `IDocumentQuery<T>` object which can be executed asynchronously. Thus not blocking the UI thread for mobile applications.

The `IDocumentQuery<T>.ExecuteNextAsync<T>` function retrieves the page of results from Azure Cosmos DB, which `HasMoreResults` checking to see if additional results remain to be returned.

> **TIP**
> Several functions that operate on Azure Cosmos containers and documents take an URI as a parameter which specifies the address of the container or document. This URI is constructed using the `URIFactory` class. URIs for databases, containers, and documents can all be created with this class.

- The `ComsmosDBService.InsertToDoItem` function demonstrates how to insert a new document:

```
/// <summary>
/// </summary>
/// <returns></returns>
public async static Task InsertToDoItem(ToDoItem item)
{
    if (!await Initialize())
        return;

    await docClient.CreateDocumentAsync(
        UriFactory.CreateDocumentCollectionUri(databaseName, collectionName),
        item);
}
```

The item URI is specified as well as the item to be inserted.

- The `CosmosDBService.UpdateToDoItem` function demonstrates how to replace an existing document with a new one:

  ```
  /// <summary>
  /// </summary>
  /// <returns></returns>
  public async static Task UpdateToDoItem(ToDoItem item)
  {
      if (!await Initialize())
          return;

      var docUri = UriFactory.CreateDocumentUri(databaseName, collectionName, item.Id);
      await docClient.ReplaceDocumentAsync(docUri, item);
  }
  ```

  Here a new URI is needed to uniquely identify the document to replace and is obtained by using `UriFactory.CreateDocumentUri` and passing it the database and container names and the ID of the document.

  The `DocumentClient.ReplaceDocumentAsync` replaces the document identified by the URI with the one specified as a parameter.

- Deleting an item is demonstrated with the `CosmosDBService.DeleteToDoItem` function:

  ```
  /// <summary>
  /// </summary>
  /// <returns></returns>
  public async static Task DeleteToDoItem(ToDoItem item)
  {
      if (!await Initialize())
          return;

      var docUri = UriFactory.CreateDocumentUri(databaseName, collectionName, item.Id);
      await docClient.DeleteDocumentAsync(docUri);
  }
  ```

  Again note the unique document URI being created and passed to the `DocumentClient.DeleteDocumentAsync` function.

Run the app

You've now updated your app with all the info it needs to communicate with Azure Cosmos DB.

The following steps will demonstrate how to run the app using the Visual Studio for Mac debugger.

> **NOTE**
>
> Usage of the Android version app is exactly the same, any differences will be called out in the steps below. If you wish to debug with Visual Studio on Windows, documentation todo so can be found for iOS here and Android here.

1. First select the platform you wish to target by clicking on the dropdown highlighted and selecting either ToDoItems.iOS for iOS or ToDoItems.Android for Android.

2. To start debugging the app, either press cmd+Enter or click the play button.

3. When the iOS simulator or Android emulator finishes launching, the app will display 2 tabs at the bottom of the screen for iOS and the top of the screen for Android. The first shows todo items which are not completed, the second shows todo items which are completed.

4. To complete a todo item on iOS, slide it to the left > tap on the **Complete** button. To complete a todo item on Android, long press the item > then tap on the complete button.

5. To edit a todo item > tap on the item > a new screen appears letting you enter new values. Tapping the save button will persist the changes to Azure Cosmos DB.

6. To add a todo item > tap on the **Add** button on the upper right of the home screen > a new, blank, edit page will appear.

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.

2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on the charts.

3. Review the metrics on the other tabs.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.

2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos account, create a container using the Data Explorer, and build and deploy a Xamarin app. You can now import additional data to your Azure Cosmos account.

Import data into Azure Cosmos DB

Tutorial: Build a .NET console app to manage data in Azure Cosmos DB SQL API account

11/2/2020 • 19 minutes to read • Edit Online

APPLIES TO: SQL API

Welcome to the Azure Cosmos DB SQL API get started tutorial. After following this tutorial, you'll have a console application that creates and queries Azure Cosmos DB resources.

This tutorial uses version 3.0 or later of the Azure Cosmos DB .NET SDK. You can work with .NET Framework or .NET Core.

This tutorial covers:

- Creating and connecting to an Azure Cosmos account
- Configuring your project in Visual Studio
- Creating a database and a container
- Adding items to the container
- Querying the container
- Performing create, read, update, and delete (CRUD) operations on the item
- Deleting the database

Don't have time? Don't worry! The complete solution is available on GitHub. Jump to the Get the complete tutorial solution section for quick instructions.

Now let's get started!

Prerequisites

- An active Azure account. If you don't have one, you can sign up for a free account.

  You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

- Download and use the free Visual Studio 2019 Community Edition. Make sure that you enable the **Azure development** workload during the Visual Studio setup.

Step 1: Create an Azure Cosmos DB account

Let's create an Azure Cosmos DB account. If you already have an account you want to use, skip this section. To use the Azure Cosmos DB Emulator, follow the steps at Azure Cosmos DB Emulator to set up the emulator. Then skip ahead to Step 2: Set up your Visual Studio project.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.

2. On the **New** page, search for and select **Azure Cosmos DB**.

3. On the **Azure Cosmos DB** page, select **Create**.

4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos

account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.

SETTING	VALUE	DESCRIPTION
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

> **NOTE**
> You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

> **NOTE**
> The following options are not available if you select **Serverless** as the **Capacity mode**:
>
> - Apply Free Tier Discount
> - Geo-redundancy
> - Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Step 2: Set up your Visual Studio project

1. Open Visual Studio and select **Create a new project**.
2. In **Create a new project**, choose **Console App (.NET Framework)** for C#, then select **Next**.
3. Name your project *CosmosGettingStartedTutorial*, and then select **Create**.

4. In the **Solution Explorer**, right-click your new console application, which is under your Visual Studio solution, and select **Manage NuGet Packages**.
5. In the **NuGet Package Manager**, select **Browse** and search for *Microsoft.Azure.Cosmos*. Choose **Microsoft.Azure.Cosmos** and select **Install**.

The package ID for the Azure Cosmos DB SQL API Client Library is Microsoft Azure Cosmos DB Client Library.

Great! Now that we finished the setup, let's start writing some code. For the completed project of this tutorial, see Developing a .NET console app using Azure Cosmos DB.

Step 3: Connect to an Azure Cosmos DB account

1. Replace the references at the beginning of your C# application in the *Program.cs* file with these references:

```
using System;
using System.Threading.Tasks;
using System.Configuration;
using System.Collections.Generic;
using System.Net;
using Microsoft.Azure.Cosmos;
```

2. Add these constants and variables into your `Program` class.

```
public class Program
{
    // ADD THIS PART TO YOUR CODE

    // The Azure Cosmos DB endpoint for running this sample.
    private static readonly string EndpointUri = "<your endpoint here>";
    // The primary key for the Azure Cosmos account.
    private static readonly string PrimaryKey = "<your primary key>";

    // The Cosmos client instance
    private CosmosClient cosmosClient;

    // The database we will create
    private Database database;

    // The container we will create.
    private Container container;

    // The name of the database and container we will create
    private string databaseId = "FamilyDatabase";
    private string containerId = "FamilyContainer";
}
```

> **NOTE**
>
> If you're familiar with the previous version of the .NET SDK, you may be familiar with the terms *collection* and *document*. Because Azure Cosmos DB supports multiple API models, version 3.0 of the .NET SDK uses the generic terms *container* and *item*. A *container* can be a collection, graph, or table. An *item* can be a document, edge/vertex, or row, and is the content inside a container. For more information, see Work with databases, containers, and items in Azure Cosmos DB.

3. Open the Azure portal. Find your Azure Cosmos DB account, and then select **Keys**.

4. In *Program.cs*, replace `<your endpoint URL>` with the value of **URI**. Replace `<your primary key>` with the value of **PRIMARY KEY**.

5. Below the **Main** method, add a new asynchronous task called **GetStartedDemoAsync**, which instantiates our new `CosmosClient`.

```
public static async Task Main(string[] args)
{
}

// ADD THIS PART TO YOUR CODE
/*
    Entry point to call methods that operate on Azure Cosmos DB resources in this sample
*/
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
}
```

   We use **GetStartedDemoAsync** as the entry point that calls methods that operate on Azure Cosmos DB resources.

6. Add the following code to run the **GetStartedDemoAsync** asynchronous task from your **Main** method. The **Main** method catches exceptions and writes them to the console.

```
public static async Task Main(string[] args)
{
    try
    {
        Console.WriteLine("Beginning operations...\n");
        Program p = new Program();
        await p.GetStartedDemoAsync();

    }
    catch (CosmosException de)
    {
        Exception baseException = de.GetBaseException();
        Console.WriteLine("{0} error occurred: {1}", de.StatusCode, de);
    }
    catch (Exception e)
    {
        Console.WriteLine("Error: {0}", e);
    }
    finally
    {
        Console.WriteLine("End of demo, press any key to exit.");
        Console.ReadKey();
    }
}
```

7. Select F5 to run your application.

   The console displays the message: **End of demo, press any key to exit.** This message confirms that your application made a connection to Azure Cosmos DB. You can then close the console window.

Congratulations! You've successfully connected to an Azure Cosmos DB account.

Step 4: Create a database

A database is the logical container of items partitioned across containers. Either the `CreateDatabaseIfNotExistsAsync` or `CreateDatabaseAsync` method of the CosmosClient class can create a database.

1. Copy and paste the `CreateDatabaseAsync` method below your `GetStartedDemoAsync` method.

```
/// <summary>
/// Create the database if it does not exist
/// </summary>
private async Task CreateDatabaseAsync()
{
    // Create a new database
    this.database = await this.cosmosClient.CreateDatabaseIfNotExistsAsync(databaseId);
    Console.WriteLine("Created Database: {0}\n", this.database.Id);
}
```

   `CreateDatabaseAsync` creates a new database with ID `FamilyDatabase` if it doesn't already exist, that has the ID specified from the `databaseId` field.

2. Copy and paste the code below where you instantiate the CosmosClient to call the **CreateDatabaseAsync** method you just added.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);

    //ADD THIS PART TO YOUR CODE
    await this.CreateDatabaseAsync();
}
```

Your *Program.cs* should now look like this, with your endpoint and primary key filled in.

```
using System;
using System.Threading.Tasks;
using System.Configuration;
using System.Collections.Generic;
using System.Net;
using Microsoft.Azure.Cosmos;

namespace CosmosGettingStartedTutorial
{
    class Program
    {
        // The Azure Cosmos DB endpoint for running this sample.
        private static readonly string EndpointUri = "<your endpoint here>";
        // The primary key for the Azure Cosmos account.
        private static readonly string PrimaryKey = "<your primary key>";

        // The Cosmos client instance
        private CosmosClient cosmosClient;

        // The database we will create
        private Database database;

        // The container we will create.
        private Container container;

        // The name of the database and container we will create
        private string databaseId = "FamilyDatabase";
        private string containerId = "FamilyContainer";

        public static async Task Main(string[] args)
        {
            try
            {
                Console.WriteLine("Beginning operations...");
                Program p = new Program();
                await p.GetStartedDemoAsync();
            }
            catch (CosmosException de)
            {
                Exception baseException = de.GetBaseException();
                Console.WriteLine("{0} error occurred: {1}\n", de.StatusCode, de);
            }
            catch (Exception e)
            {
                Console.WriteLine("Error: {0}\n", e);
            }
            finally
            {
                Console.WriteLine("End of demo, press any key to exit.");
                Console.ReadKey();
            }
        }

        /// <summary>
        /// Entry point to call methods that operate on Azure Cosmos DB resources in this sample
```

```
        /// </summary>
        public async Task GetStartedDemoAsync()
        {
            // Create a new instance of the Cosmos Client
            this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
            await this.CreateDatabaseAsync();
        }

        /// <summary>
        /// Create the database if it does not exist
        /// </summary>
        private async Task CreateDatabaseAsync()
        {
            // Create a new database
            this.database = await this.cosmosClient.CreateDatabaseIfNotExistsAsync(databaseId);
            Console.WriteLine("Created Database: {0}\n", this.database.Id);
        }
    }
}
```

3. Select F5 to run your application.

> **NOTE**
>
> If you get a "503 service unavailable exception" error, it's possible that the required ports for direct connectivity mode are blocked by a firewall. To fix this issue, either open the required ports or use the gateway mode connectivity as shown in the following code:

```
// Create a new instance of the Cosmos Client in Gateway mode
this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey, new CosmosClientOptions()
       {
           ConnectionMode = ConnectionMode.Gateway
       });
```

Congratulations! You've successfully created an Azure Cosmos database.

Step 5: Create a container

> **WARNING**
>
> The method `CreateContainerIfNotExistsAsync` creates a new container, which has pricing implications. For more details, please visit our pricing page.

A container can be created by using either the **CreateContainerIfNotExistsAsync** or **CreateContainerAsync** method in the `CosmosDatabase` class. A container consists of items (JSON documents if SQL API) and associated server-side application logic in JavaScript, for example, stored procedures, user-defined functions, and triggers.

1. Copy and paste the `CreateContainerAsync` method below your `CreateDatabaseAsync` method. `CreateContainerAsync` creates a new container with the ID `FamilyContainer` if it doesn't already exist, by using the ID specified from the `containerId` field partitioned by `LastName` property.

```
/// <summary>
/// Create the container if it does not exist.
/// Specifiy "/LastName" as the partition key since we're storing family information, to ensure good
distribution of requests and storage.
/// </summary>
/// <returns></returns>
private async Task CreateContainerAsync()
{
    // Create a new container
    this.container = await this.database.CreateContainerIfNotExistsAsync(containerId, "/LastName");
    Console.WriteLine("Created Container: {0}\n", this.container.Id);
}
```

2. Copy and paste the code below where you instantiated the CosmosClient to call the **CreateContainer** method you just added.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
    await this.CreateDatabaseAsync();

    //ADD THIS PART TO YOUR CODE
    await this.CreateContainerAsync();
}
```

3. Select F5 to run your application.

Congratulations! You've successfully created an Azure Cosmos container.

Step 6: Add items to the container

The **CreateItemAsync** method of the `CosmosContainer` class can create an item. When using the SQL API, items are projected as documents, which are user-defined arbitrary JSON content. You can now insert an item into your Azure Cosmos container.

First, let's create a `Family` class that represents objects stored within Azure Cosmos DB in this sample. We'll also create `Parent`, `Child`, `Pet`, `Address` subclasses that are used within `Family`. The item must have an `Id` property serialized as `id` in JSON.

1. Select Ctrl+Shift+A to open **Add New Item**. Add a new class `Family.cs` to your project.

2. Copy and paste the `Family`, `Parent`, `Child`, `Pet`, and `Address` class into `Family.cs`.

```
using Newtonsoft.Json;

namespace CosmosGettingStartedTutorial
{
    public class Family
    {
        [JsonProperty(PropertyName = "id")]
        public string Id { get; set; }
        public string LastName { get; set; }
        public Parent[] Parents { get; set; }
        public Child[] Children { get; set; }
        public Address Address { get; set; }
        public bool IsRegistered { get; set; }
        public override string ToString()
        {
            return JsonConvert.SerializeObject(this);
        }
    }

    public class Parent
    {
        public string FamilyName { get; set; }
        public string FirstName { get; set; }
    }

    public class Child
    {
        public string FamilyName { get; set; }
        public string FirstName { get; set; }
        public string Gender { get; set; }
        public int Grade { get; set; }
        public Pet[] Pets { get; set; }
    }

    public class Pet
    {
        public string GivenName { get; set; }
    }

    public class Address
    {
        public string State { get; set; }
        public string County { get; set; }
        public string City { get; set; }
    }
}
```

3. Back in *Program.cs*, add the `AddItemsToContainerAsync` method after your `CreateContainerAsync` method.

```
/// <summary>
/// Add Family items to the container
/// </summary>
private async Task AddItemsToContainerAsync()
{
    // Create a family object for the Andersen family
    Family andersenFamily = new Family
    {
        Id = "Andersen.1",
        LastName = "Andersen",
        Parents = new Parent[]
        {
            new Parent { FirstName = "Thomas" },
            new Parent { FirstName = "Mary Kay" }
        },
```

```
        Children = new Child[]
        {
            new Child
            {
                FirstName = "Henriette Thaulow",
                Gender = "female",
                Grade = 5,
                Pets = new Pet[]
                {
                    new Pet { GivenName = "Fluffy" }
                }
            }
        },
        Address = new Address { State = "WA", County = "King", City = "Seattle" },
        IsRegistered = false
    };

    try
    {
        // Read the item to see if it exists.
        ItemResponse<Family> andersenFamilyResponse = await this.container.ReadItemAsync<Family>
(andersenFamily.Id, new PartitionKey(andersenFamily.LastName));
        Console.WriteLine("Item in database with id: {0} already exists\n",
andersenFamilyResponse.Resource.Id);
    }
    catch(CosmosException ex) when (ex.StatusCode == HttpStatusCode.NotFound)
    {
        // Create an item in the container representing the Andersen family. Note we provide the value
of the partition key for this item, which is "Andersen"
        ItemResponse<Family> andersenFamilyResponse = await this.container.CreateItemAsync<Family>
(andersenFamily, new PartitionKey(andersenFamily.LastName));

        // Note that after creating the item, we can access the body of the item with the Resource
property off the ItemResponse. We can also access the RequestCharge property to see the amount of RUs
consumed on this request.
        Console.WriteLine("Created item in database with id: {0} Operation consumed {1} RUs.\n",
andersenFamilyResponse.Resource.Id, andersenFamilyResponse.RequestCharge);
    }

    // Create a family object for the Wakefield family
    Family wakefieldFamily = new Family
    {
        Id = "Wakefield.7",
        LastName = "Wakefield",
        Parents = new Parent[]
        {
            new Parent { FamilyName = "Wakefield", FirstName = "Robin" },
            new Parent { FamilyName = "Miller", FirstName = "Ben" }
        },
        Children = new Child[]
        {
            new Child
            {
                FamilyName = "Merriam",
                FirstName = "Jesse",
                Gender = "female",
                Grade = 8,
                Pets = new Pet[]
                {
                    new Pet { GivenName = "Goofy" },
                    new Pet { GivenName = "Shadow" }
                }
            },
            new Child
            {
                FamilyName = "Miller",
                FirstName = "Lisa",
                Gender = "female",
                Grade = 1
```

```
            }
        },
        Address = new Address { State = "NY", County = "Manhattan", City = "NY" },
        IsRegistered = true
    };

    try
    {
        // Read the item to see if it exists
        ItemResponse<Family> wakefieldFamilyResponse = await this.container.ReadItemAsync<Family>
(wakefieldFamily.Id, new PartitionKey(wakefieldFamily.LastName));
        Console.WriteLine("Item in database with id: {0} already exists\n",
wakefieldFamilyResponse.Resource.Id);
    }
    catch(CosmosException ex) when (ex.StatusCode == HttpStatusCode.NotFound)
    {
        // Create an item in the container representing the Wakefield family. Note we provide the value
of the partition key for this item, which is "Wakefield"
        ItemResponse<Family> wakefieldFamilyResponse = await this.container.CreateItemAsync<Family>
(wakefieldFamily, new PartitionKey(wakefieldFamily.LastName));

        // Note that after creating the item, we can access the body of the item with the Resource
property off the ItemResponse. We can also access the RequestCharge property to see the amount of RUs
consumed on this request.
        Console.WriteLine("Created item in database with id: {0} Operation consumed {1} RUs.\n",
wakefieldFamilyResponse.Resource.Id, wakefieldFamilyResponse.RequestCharge);
    }
}
```

The code checks to make sure an item with the same ID doesn't already exist. We'll insert two items, one each for the *Andersen Family* and the *Wakefield Family*.

4. Add a call to `AddItemsToContainerAsync` in the `GetStartedDemoAsync` method.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
    await this.CreateDatabaseAsync();
    await this.CreateContainerAsync();

    //ADD THIS PART TO YOUR CODE
    await this.AddItemsToContainerAsync();
}
```

5. Select F5 to run your application.

Congratulations! You've successfully created two Azure Cosmos items.

Step 7: Query Azure Cosmos DB resources

Azure Cosmos DB supports rich queries against JSON documents stored in each container. For more information, see Getting started with SQL queries. The following sample code shows how to run a query against the items we inserted in the previous step.

1. Copy and paste the `QueryItemsAsync` method after your `AddItemsToContainerAsync` method.

```
/// <summary>
/// Run a query (using Azure Cosmos DB SQL syntax) against the container
/// </summary>
private async Task QueryItemsAsync()
{
    var sqlQueryText = "SELECT * FROM c WHERE c.LastName = 'Andersen'";

    Console.WriteLine("Running query: {0}\n", sqlQueryText);

    QueryDefinition queryDefinition = new QueryDefinition(sqlQueryText);
    FeedIterator<Family> queryResultSetIterator = this.container.GetItemQueryIterator<Family>
(queryDefinition);

    List<Family> families = new List<Family>();

    while (queryResultSetIterator.HasMoreResults)
    {
        FeedResponse<Family> currentResultSet = await queryResultSetIterator.ReadNextAsync();
        foreach (Family family in currentResultSet)
        {
            families.Add(family);
            Console.WriteLine("\tRead {0}\n", family);
        }
    }
}
```

2. Add a call to `QueryItemsAsync` in the `GetStartedDemoAsync` method.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
    await this.CreateDatabaseAsync();
    await this.CreateContainerAsync();
    await this.AddItemsToContainerAsync();

    //ADD THIS PART TO YOUR CODE
    await this.QueryItemsAsync();
}
```

3. Select F5 to run your application.

Congratulations! You've successfully queried an Azure Cosmos container.

Step 8: Replace a JSON item

Now, we'll update an item in Azure Cosmos DB. We'll change the `IsRegistered` property of the `Family` and the `Grade` of one of the children.

1. Copy and paste the `ReplaceFamilyItemAsync` method after your `QueryItemsAsync` method.

```
/// <summary>
/// Replace an item in the container
/// </summary>
private async Task ReplaceFamilyItemAsync()
{
    ItemResponse<Family> wakefieldFamilyResponse = await this.container.ReadItemAsync<Family>
("Wakefield.7", new PartitionKey("Wakefield"));
    var itemBody = wakefieldFamilyResponse.Resource;

    // update registration status from false to true
    itemBody.IsRegistered = true;
    // update grade of child
    itemBody.Children[0].Grade = 6;

    // replace the item with the updated content
    wakefieldFamilyResponse = await this.container.ReplaceItemAsync<Family>(itemBody, itemBody.Id, new
PartitionKey(itemBody.LastName));
    Console.WriteLine("Updated Family [{0},{1}].\n \tBody is now: {2}\n", itemBody.LastName,
itemBody.Id, wakefieldFamilyResponse.Resource);
}
```

2. Add a call to `ReplaceFamilyItemAsync` in the `GetStartedDemoAsync` method.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
    await this.CreateDatabaseAsync();
    await this.CreateContainerAsync();
    await this.AddItemsToContainerAsync();
    await this.QueryItemsAsync();

    //ADD THIS PART TO YOUR CODE
    await this.ReplaceFamilyItemAsync();
}
```

3. Select F5 to run your application.

Congratulations! You've successfully replaced an Azure Cosmos item.

Step 9: Delete item

Now, we'll delete an item in Azure Cosmos DB.

1. Copy and paste the `DeleteFamilyItemAsync` method after your `ReplaceFamilyItemAsync` method.

```
/// <summary>
/// Delete an item in the container
/// </summary>
private async Task DeleteFamilyItemAsync()
{
    var partitionKeyValue = "Wakefield";
    var familyId = "Wakefield.7";

    // Delete an item. Note we must provide the partition key value and id of the item to delete
    ItemResponse<Family> wakefieldFamilyResponse = await this.container.DeleteItemAsync<Family>
(familyId,new PartitionKey(partitionKeyValue));
    Console.WriteLine("Deleted Family [{0},{1}]\n", partitionKeyValue, familyId);
}
```

2. Add a call to `DeleteFamilyItemAsync` in the `GetStartedDemoAsync` method.

```
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
    await this.CreateDatabaseAsync();
    await this.CreateContainerAsync();
    await this.AddItemsToContainerAsync();
    await this.QueryItemsAsync();
    await this.ReplaceFamilyItemAsync();

    //ADD THIS PART TO YOUR CODE
    await this.DeleteFamilyItemAsync();
}
```

3. Select F5 to run your application.

Congratulations! You've successfully deleted an Azure Cosmos item.

Step 10: Delete the database

Now we'll delete our database. Deleting the created database removes the database and all children resources. The resources include containers, items, and any stored procedures, user-defined functions, and triggers. We also dispose of the `CosmosClient` instance.

1. Copy and paste the `DeleteDatabaseAndCleanupAsync` method after your `DeleteFamilyItemAsync` method.

```
/// <summary>
/// Delete the database and dispose of the Cosmos Client instance
/// </summary>
private async Task DeleteDatabaseAndCleanupAsync()
{
    DatabaseResponse databaseResourceResponse = await this.database.DeleteAsync();
    // Also valid: await this.cosmosClient.Databases["FamilyDatabase"].DeleteAsync();

    Console.WriteLine("Deleted Database: {0}\n", this.databaseId);

    //Dispose of CosmosClient
    this.cosmosClient.Dispose();
}
```

2. Add a call to `DeleteDatabaseAndCleanupAsync` in the `GetStartedDemoAsync` method.

```
/// <summary>
/// Entry point to call methods that operate on Azure Cosmos DB resources in this sample
/// </summary>
public async Task GetStartedDemoAsync()
{
    // Create a new instance of the Cosmos Client
    this.cosmosClient = new CosmosClient(EndpointUri, PrimaryKey);
    await this.CreateDatabaseAsync();
    await this.CreateContainerAsync();
    await this.AddItemsToContainerAsync();
    await this.QueryItemsAsync();
    await this.ReplaceFamilyItemAsync();
    await this.DeleteFamilyItemAsync();
    await this.DeleteDatabaseAndCleanupAsync();
}
```

3. Select F5 to run your application.

Congratulations! You've successfully deleted an Azure Cosmos database.

Step 11: Run your C# console application all together!

Select F5 in Visual Studio to build and run the application in debug mode.

You should see the output of your entire app in a console window. The output shows the results of the queries we added. It should match the example text below.

```
Beginning operations...

Created Database: FamilyDatabase

Created Container: FamilyContainer

Created item in database with id: Andersen.1 Operation consumed 11.43 RUs.

Created item in database with id: Wakefield.7 Operation consumed 14.29 RUs.

Running query: SELECT * FROM c WHERE c.LastName = 'Andersen'

        Read {"id":"Andersen.1","LastName":"Andersen","Parents":[{"FamilyName":null,"FirstName":"Thomas"},
{"FamilyName":null,"FirstName":"Mary Kay"}],"Children":[{"FamilyName":null,"FirstName":"Henriette
Thaulow","Gender":"female","Grade":5,"Pets":[{"GivenName":"Fluffy"}]}],"Address":
{"State":"WA","County":"King","City":"Seattle"},"IsRegistered":false}

Updated Family [Wakefield,Wakefield.7].
        Body is now: {"id":"Wakefield.7","LastName":"Wakefield","Parents":
[{"FamilyName":"Wakefield","FirstName":"Robin"},{"FamilyName":"Miller","FirstName":"Ben"}],"Children":
[{"FamilyName":"Merriam","FirstName":"Jesse","Gender":"female","Grade":6,"Pets":[{"GivenName":"Goofy"},
{"GivenName":"Shadow"}]},
{"FamilyName":"Miller","FirstName":"Lisa","Gender":"female","Grade":1,"Pets":null}],"Address":
{"State":"NY","County":"Manhattan","City":"NY"},"IsRegistered":true}

Deleted Family [Wakefield,Wakefield.7]

Deleted Database: FamilyDatabase

End of demo, press any key to exit.
```

Congratulations! You've completed the tutorial and have a working C# console application!

Get the complete tutorial solution

If you didn't have time to complete the steps in this tutorial, or just want to download the code samples, you can download it.

To build the `GetStarted` solution, you need the following prerequisites:

- An active Azure account. If you don't have one, you can sign up for a free account.
- An Azure Cosmos DB account.
- The GetStarted solution available on GitHub.

To restore the references to the Azure Cosmos DB .NET SDK in Visual Studio, right-click the solution in **Solution Explorer**, and then select **Restore NuGet Packages**. Next, in the *App.config* file, update the `EndPointUri` and `PrimaryKey` values as described in Step 3: Connect to an Azure Cosmos DB account.

That's it, build it, and you're on your way!

Next steps

- Want a more complex ASP.NET MVC tutorial? See Tutorial: Develop an ASP.NET Core MVC web application with Azure Cosmos DB by using .NET SDK.

- Want to do scale and performance testing with Azure Cosmos DB? See Performance and scale testing with Azure Cosmos DB.
- To learn how to monitor Azure Cosmos DB requests, usage, and storage, see Monitor performance and storage metrics in Azure Cosmos DB.
- To run queries against our sample dataset, see the Query Playground.
- To learn more about Azure Cosmos DB, see Welcome to Azure Cosmos DB.

Quickstart: Build a Java app to manage Azure Cosmos DB SQL API data

11/2/2020 • 15 minutes to read • Edit Online

APPLIES TO: SQL API

In this quickstart, you create and manage an Azure Cosmos DB SQL API account from the Azure portal, and by using a Java app cloned from GitHub. First, you create an Azure Cosmos DB SQL API account using the Azure portal, then create a Java app using the SQL Java SDK, and then add resources to your Cosmos DB account by using the Java application. Azure Cosmos DB is a multi-model database service that lets you quickly create and query document, table, key-value, and graph databases with global distribution and horizontal scale capabilities.

> **IMPORTANT**
>
> This quickstart is for Azure Cosmos DB Java SDK v4 only. Please view the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, Azure Cosmos DB Java SDK v4 performance tips, and Azure Cosmos DB Java SDK v4 troubleshooting guide for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

Prerequisites

- An Azure account with an active subscription. Create one for free. Or try Azure Cosmos DB for free without an Azure subscription. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081` and the key `C2y6yDjf5/R+ob0N8A7Cgv30VRDJIWEHLM+4QDU5DE2nQ9nDuVTqobD4b8mGGyPMbIZnqyMsEcaGQy67XIw/Jw==`.
- Java Development Kit (JDK) 8. Point your `JAVA_HOME` environment variable to the folder where the JDK is installed.
- A Maven binary archive. On Ubuntu, run `apt-get install maven` to install Maven.
- Git. On Ubuntu, run `sudo apt-get install git` to install Git.

Introductory notes

The structure of a Cosmos DB account. Irrespective of API or programming language, a Cosmos DB *account* contains zero or more *databases*, a *database* (DB) contains zero or more *containers*, and a *container* contains zero or more items, as shown in the diagram below:

You may read more about databases, containers and items here. A few important properties are defined at the level of the container, among them *provisioned throughput* and *partition key*.

The provisioned throughput is measured in Request Units (*RUs*) which have a monetary price and are a substantial determining factor in the operating cost of the account. Provisioned throughput can be selected at per-container granularity or per-database granularity, however container-level throughput specification is typically preferred. You may read more about throughput provisioning here.

As items are inserted into a Cosmos DB container, the database grows horizontally by adding more storage and compute to handle requests. Storage and compute capacity are added in discrete units known as *partitions*, and you must choose one field in your documents to be the partition key which maps each document to a partition. The way partitions are managed is that each partition is assigned a roughly equal slice out of the range of partition key values; therefore you are advised to choose a partition key which is relatively random or evenly-distributed. Otherwise, some partitions will see substantially more requests (*hot partition*) while other partitions see substantially fewer requests (*cold partition*), and this is to be avoided. You may learn more about partitioning here.

Create a database account

Before you can create a document database, you need to create a SQL API account with Azure Cosmos DB.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.

SETTING	VALUE	DESCRIPTION
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

> **NOTE**
>
> You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

> **NOTE**
>
> The following options are not available if you select **Serverless** as the **Capacity mode**:
>
> - Apply Free Tier Discount
> - Geo-redundancy
> - Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the uniqueness of one or

more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's switch to working with code. Let's clone a SQL API app from GitHub, set the connection string, and run it. You'll see how easy it is to work with data programmatically.

Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

```
git clone https://github.com/Azure-Samples/azure-cosmos-java-getting-started.git
```

Review the code

This step is optional. If you're interested in learning how the database resources are created in the code, you can review the following snippets. Otherwise, you can skip ahead to Run the app .

- Sync API
- Async API

Managing database resources using the synchronous (sync) API

- `CosmosClient` initialization. The `CosmosClient` provides client-side logical representation for the Azure Cosmos database service. This client is used to configure and execute requests against the service.

```
client = new CosmosClientBuilder()
    .endpoint(AccountSettings.HOST)
    .key(AccountSettings.MASTER_KEY)
    //  Setting the preferred location to Cosmos DB Account region
    //  West US is just an example. User should set preferred location to the Cosmos DB region closest
to the application
    .preferredRegions(Collections.singletonList("West US"))
    .consistencyLevel(ConsistencyLevel.EVENTUAL)
    .buildClient();
```

- `CosmosDatabase` creation.

```
CosmosDatabaseResponse cosmosDatabaseResponse = client.createDatabaseIfNotExists(databaseName);
database = client.getDatabase(cosmosDatabaseResponse.getProperties().getId());
```

- `CosmosContainer` creation.

```
CosmosContainerProperties containerProperties =
    new CosmosContainerProperties(containerName, "/lastName");

//  Create container with 400 RU/s
CosmosContainerResponse cosmosContainerResponse =
    database.createContainerIfNotExists(containerProperties,
ThroughputProperties.createManualThroughput(400));
container = database.getContainer(cosmosContainerResponse.getProperties().getId());
```

- Item creation by using the `createItem` method.

```
//  Create item using container that we created using sync client

//  Use lastName as partitionKey for cosmos item
//  Using appropriate partition key improves the performance of database operations
CosmosItemRequestOptions cosmosItemRequestOptions = new CosmosItemRequestOptions();
CosmosItemResponse<Family> item = container.createItem(family, new PartitionKey(family.getLastName()),
cosmosItemRequestOptions);
```

- Point reads are performed using `readItem` method.

```
try {
    CosmosItemResponse<Family> item = container.readItem(family.getId(), new
PartitionKey(family.getLastName()), Family.class);
    double requestCharge = item.getRequestCharge();
    Duration requestLatency = item.getDuration();
    logger.info("Item successfully read with id {} with a charge of {} and within duration {}",
        item.getItem().getId(), requestCharge, requestLatency);
} catch (CosmosException e) {
    logger.error("Read Item failed with", e);
}
```

- SQL queries over JSON are performed using the `queryItems` method.

```
// Set some common query options
CosmosQueryRequestOptions queryOptions = new CosmosQueryRequestOptions();
//queryOptions.setEnableCrossPartitionQuery(true); //No longer necessary in SDK v4
//  Set query metrics enabled to get metrics around query executions
queryOptions.setQueryMetricsEnabled(true);

CosmosPagedIterable<Family> familiesPagedIterable = container.queryItems(
    "SELECT * FROM Family WHERE Family.lastName IN ('Andersen', 'Wakefield', 'Johnson')", queryOptions,
Family.class);

familiesPagedIterable.iterableByPage(10).forEach(cosmosItemPropertiesFeedResponse -> {
    logger.info("Got a page of query result with {} items(s) and request charge of {}",
            cosmosItemPropertiesFeedResponse.getResults().size(),
cosmosItemPropertiesFeedResponse.getRequestCharge());

    logger.info("Item Ids {}", cosmosItemPropertiesFeedResponse
        .getResults()
        .stream()
        .map(Family::getId)
        .collect(Collectors.toList()));
});
```

Run the app

Now go back to the Azure portal to get your connection string information and launch the app with your endpoint information. This enables your app to communicate with your hosted database.

1. In the git terminal window, `cd` to the sample code folder.

   ```
   cd azure-cosmos-java-getting-started
   ```

2. In the git terminal window, use the following command to install the required Java packages.

   ```
   mvn package
   ```

3. In the git terminal window, use the following command to start the Java application (replace SYNCASYNCMODE with `sync` or `async` depending on which sample code you would like to run, replace YOUR_COSMOS_DB_HOSTNAME with the quoted URI value from the portal, and replace YOUR_COSMOS_DB_MASTER_KEY with the quoted primary key from portal)

   ```
   mvn exec:java@SYNCASYNCMODE -DACCOUNT_HOST=YOUR_COSMOS_DB_HOSTNAME -
   DACCOUNT_KEY=YOUR_COSMOS_DB_MASTER_KEY
   ```

   The terminal window displays a notification that the FamilyDB database was created.

4. The app creates database with name `AzureSampleFamilyDB`
5. The app creates container with name `FamilyContainer`
6. The app will perform point reads using object IDs and partition key value (which is lastName in our sample).
7. The app will query items to retrieve all families with last name in ('Andersen', 'Wakefield', 'Johnson')
8. The app doesn't delete the created resources. Switch back to the portal to clean up the resources. from your account so that you don't incur charges.

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.
2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on the charts.

3. Review the metrics on the other tabs.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.
2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos DB SQL API account, create a document database and container using the Data Explorer, and run a Java app to do the same thing programmatically. You can now import additional data into your Azure Cosmos DB account.

Import data into Azure Cosmos DB

Quickstart: Build a Java app to manage Azure Cosmos DB SQL API data

11/2/2020 • 15 minutes to read • Edit Online

APPLIES TO: SQL API

In this quickstart, you create and manage an Azure Cosmos DB SQL API account from the Azure portal, and by using a Java app cloned from GitHub. First, you create an Azure Cosmos DB SQL API account using the Azure portal, then create a Java app using the SQL Java SDK, and then add resources to your Cosmos DB account by using the Java application. Azure Cosmos DB is a multi-model database service that lets you quickly create and query document, table, key-value, and graph databases with global distribution and horizontal scale capabilities.

> **IMPORTANT**
>
> This quickstart is for Azure Cosmos DB Java SDK v4 only. Please view the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, Azure Cosmos DB Java SDK v4 performance tips, and Azure Cosmos DB Java SDK v4 troubleshooting guide for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

Prerequisites

- An Azure account with an active subscription. Create one for free. Or try Azure Cosmos DB for free without an Azure subscription. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081` and the key `C2y6yDjf5/R+ob0N8A7Cgv30VRDJIWEHLM+4QDU5DE2nQ9nDuVTqobD4b8mGGyPMbIZnqyMsEcaGQy67XIw/Jw==`.
- Java Development Kit (JDK) 8. Point your `JAVA_HOME` environment variable to the folder where the JDK is installed.
- A Maven binary archive. On Ubuntu, run `apt-get install maven` to install Maven.
- Git. On Ubuntu, run `sudo apt-get install git` to install Git.

Introductory notes

The structure of a Cosmos DB account. Irrespective of API or programming language, a Cosmos DB *account* contains zero or more *databases*, a *database* (DB) contains zero or more *containers*, and a *container* contains zero or more items, as shown in the diagram below:

You may read more about databases, containers and items here. A few important properties are defined at the level of the container, among them *provisioned throughput* and *partition key*.

The provisioned throughput is measured in Request Units (*RUs*) which have a monetary price and are a substantial determining factor in the operating cost of the account. Provisioned throughput can be selected at per-container granularity or per-database granularity, however container-level throughput specification is typically preferred. You may read more about throughput provisioning here.

As items are inserted into a Cosmos DB container, the database grows horizontally by adding more storage and compute to handle requests. Storage and compute capacity are added in discrete units known as *partitions*, and you must choose one field in your documents to be the partition key which maps each document to a partition. The way partitions are managed is that each partition is assigned a roughly equal slice out of the range of partition key values; therefore you are advised to choose a partition key which is relatively random or evenly-distributed. Otherwise, some partitions will see substantially more requests (*hot partition*) while other partitions see substantially fewer requests (*cold partition*), and this is to be avoided. You may learn more about partitioning here.

Create a database account

Before you can create a document database, you need to create a SQL API account with Azure Cosmos DB.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.

SETTING	VALUE	DESCRIPTION
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

> **NOTE**
>
> You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

> **NOTE**
>
> The following options are not available if you select **Serverless** as the **Capacity mode**:
>
> - Apply Free Tier Discount
> - Geo-redundancy
> - Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Add a container

You can now use the Data Explorer tool in the Azure portal to create a database and container.

1. Select **Data Explorer** > **New Container**.

   The **Add Container** area is displayed on the far right, you may need to scroll right to see it.

2. In the **Add container** page, enter the settings for the new container.

SETTING	SUGGESTED VALUE	DESCRIPTION
Database ID	Tasks	Enter *Tasks* as the name for the new database. Database names must contain from 1 through 255 characters, and they cannot contain `/, \\, #, ?`, or a trailing space. Check the **Provision database throughput** option, it allows you to share the throughput provisioned to the database across all the containers within the database. This option also helps with cost savings.
Throughput	400	Leave the throughput at 400 request units per second (RU/s). If you want to reduce latency, you can scale up the throughput later.
Container ID	Items	Enter *Items* as the name for your new container. Container IDs have the same character requirements as database names.
Partition key	/category	The sample described in this article uses */category* as the partition key.

In addition to the preceding settings, you can optionally add **Unique keys** for the container. Let's leave the field empty in this example. Unique keys provide developers with the ability to add a layer of data integrity to the database. By creating a unique key policy while creating a container, you ensure the

uniqueness of one or more values per partition key. To learn more, refer to the Unique keys in Azure Cosmos DB article.

Select **OK**. The Data Explorer displays the new database and container.

Add sample data

You can now add data to your new container using Data Explorer.

1. From the **Data Explorer**, expand the **Tasks** database, expand the **Items** container. Select **Items**, and then select **New Item**.

2. Now add a document to the container with the following structure.

```
{
    "id": "1",
    "category": "personal",
    "name": "groceries",
    "description": "Pick up apples and strawberries.",
    "isComplete": false
}
```

3. Once you've added the json to the **Documents** tab, select **Save**.

4. Create and save one more document where you insert a unique value for the `id` property, and change the other properties as you see fit. Your new documents can have any structure you want as Azure Cosmos DB doesn't impose any schema on your data.

Query your data

You can use queries in Data Explorer to retrieve and filter your data.

1. At the top of the **Items** tab in Data Explorer, review the default query `SELECT * FROM c`. This query retrieves and displays all documents from the container ordered by ID.

2. To change the query, select **Edit Filter**, replace the default query with `ORDER BY c._ts DESC`, and then select **Apply Filter**.

The modified query displays the documents in descending order based on their time stamp, so now your second document is listed first.

If you're familiar with SQL syntax, you can enter any supported SQL queries in the query predicate box. You can also use Data Explorer to create stored procedures, UDFs, and triggers for server-side business logic.

Data Explorer provides easy Azure portal access to all of the built-in programmatic data access features available in the APIs. You also use the portal to scale throughput, get keys and connection strings, and review metrics and SLAs for your Azure Cosmos DB account.

Clone the sample application

Now let's switch to working with code. Let's clone a SQL API app from GitHub, set the connection string, and run it. You'll see how easy it is to work with data programmatically.

Run the following command to clone the sample repository. This command creates a copy of the sample app on your computer.

```
git clone https://github.com/Azure-Samples/azure-cosmos-java-getting-started.git
```

Review the code

This step is optional. If you're interested in learning how the database resources are created in the code, you can review the following snippets. Otherwise, you can skip ahead to Run the app .

- Sync API
- Async API

Managing database resources using the synchronous (sync) API

- `CosmosClient` initialization. The `CosmosClient` provides client-side logical representation for the Azure Cosmos database service. This client is used to configure and execute requests against the service.

```
client = new CosmosClientBuilder()
    .endpoint(AccountSettings.HOST)
    .key(AccountSettings.MASTER_KEY)
    //  Setting the preferred location to Cosmos DB Account region
    //  West US is just an example. User should set preferred location to the Cosmos DB region
closest to the application
    .preferredRegions(Collections.singletonList("West US"))
    .consistencyLevel(ConsistencyLevel.EVENTUAL)
    .buildClient();
```

- `CosmosDatabase` creation.

```
CosmosDatabaseResponse cosmosDatabaseResponse = client.createDatabaseIfNotExists(databaseName);
database = client.getDatabase(cosmosDatabaseResponse.getProperties().getId());
```

- `CosmosContainer` creation.

```
CosmosContainerProperties containerProperties =
    new CosmosContainerProperties(containerName, "/lastName");

//  Create container with 400 RU/s
CosmosContainerResponse cosmosContainerResponse =
    database.createContainerIfNotExists(containerProperties,
ThroughputProperties.createManualThroughput(400));
container = database.getContainer(cosmosContainerResponse.getProperties().getId());
```

- Item creation by using the `createItem` method.

```
//  Create item using container that we created using sync client

//  Use lastName as partitionKey for cosmos item
//  Using appropriate partition key improves the performance of database operations
CosmosItemRequestOptions cosmosItemRequestOptions = new CosmosItemRequestOptions();
CosmosItemResponse<Family> item = container.createItem(family, new
PartitionKey(family.getLastName()), cosmosItemRequestOptions);
```

- Point reads are performed using `readItem` method.

```
try {
    CosmosItemResponse<Family> item = container.readItem(family.getId(), new
PartitionKey(family.getLastName()), Family.class);
    double requestCharge = item.getRequestCharge();
    Duration requestLatency = item.getDuration();
    logger.info("Item successfully read with id {} with a charge of {} and within duration {}",
        item.getItem().getId(), requestCharge, requestLatency);
} catch (CosmosException e) {
    logger.error("Read Item failed with", e);
}
```

- SQL queries over JSON are performed using the `queryItems` method.

```
// Set some common query options
CosmosQueryRequestOptions queryOptions = new CosmosQueryRequestOptions();
//queryOptions.setEnableCrossPartitionQuery(true); //No longer necessary in SDK v4
//  Set query metrics enabled to get metrics around query executions
queryOptions.setQueryMetricsEnabled(true);

CosmosPagedIterable<Family> familiesPagedIterable = container.queryItems(
    "SELECT * FROM Family WHERE Family.lastName IN ('Andersen', 'Wakefield', 'Johnson')",
queryOptions, Family.class);

familiesPagedIterable.iterableByPage(10).forEach(cosmosItemPropertiesFeedResponse -> {
    logger.info("Got a page of query result with {} items(s) and request charge of {}",
            cosmosItemPropertiesFeedResponse.getResults().size(),
cosmosItemPropertiesFeedResponse.getRequestCharge());

    logger.info("Item Ids {}", cosmosItemPropertiesFeedResponse
        .getResults()
        .stream()
        .map(Family::getId)
        .collect(Collectors.toList()));
});
```

Run the app

Now go back to the Azure portal to get your connection string information and launch the app with your endpoint information. This enables your app to communicate with your hosted database.

1. In the git terminal window, `cd` to the sample code folder.

   ```
   cd azure-cosmos-java-getting-started
   ```

2. In the git terminal window, use the following command to install the required Java packages.

   ```
   mvn package
   ```

3. In the git terminal window, use the following command to start the Java application (replace SYNCASYNCMODE with `sync` or `async` depending on which sample code you would like to run, replace YOUR_COSMOS_DB_HOSTNAME with the quoted URI value from the portal, and replace YOUR_COSMOS_DB_MASTER_KEY with the quoted primary key from portal)

   ```
   mvn exec:java@SYNCASYNCMODE -DACCOUNT_HOST=YOUR_COSMOS_DB_HOSTNAME -
   DACCOUNT_KEY=YOUR_COSMOS_DB_MASTER_KEY
   ```

   The terminal window displays a notification that the FamilyDB database was created.

4. The app creates database with name `AzureSampleFamilyDB`

5. The app creates container with name `FamilyContainer`

6. The app will perform point reads using object IDs and partition key value (which is lastName in our sample).

7. The app will query items to retrieve all families with last name in ('Andersen', 'Wakefield', 'Johnson')

8. The app doesn't delete the created resources. Switch back to the portal to clean up the resources. from your account so that you don't incur charges.

Review SLAs in the Azure portal

The Azure portal monitors your Cosmos DB account throughput, storage, availability, latency, and consistency. Charts for metrics associated with an Azure Cosmos DB Service Level Agreement (SLA) show the SLA value compared to actual performance. This suite of metrics makes monitoring your SLAs transparent.

To review metrics and SLAs:

1. Select **Metrics** in your Cosmos DB account's navigation menu.
2. Select a tab such as **Latency**, and select a timeframe on the right. Compare the **Actual** and **SLA** lines on the charts.

3. Review the metrics on the other tabs.

Clean up resources

When you're done with your app and Azure Cosmos DB account, you can delete the Azure resources you created so you don't incur more charges. To delete the resources:

1. In the Azure portal Search bar, search for and select **Resource groups**.
2. From the list, select the resource group you created for this quickstart.

3. On the resource group **Overview** page, select **Delete resource group**.

4. In the next window, enter the name of the resource group to delete, and then select **Delete**.

Next steps

In this quickstart, you've learned how to create an Azure Cosmos DB SQL API account, create a document database and container using the Data Explorer, and run a Java app to do the same thing programmatically. You can now import additional data into your Azure Cosmos DB account.

Import data into Azure Cosmos DB

Tutorial: Build a Node.js console app with the JavaScript SDK to manage Azure Cosmos DB SQL API data

11/2/2020 • 11 minutes to read • Edit Online

APPLIES TO: SQL API

As a developer, you might have applications that use NoSQL document data. You can use a SQL API account in Azure Cosmos DB to store and access this document data. This tutorial shows you how to build a Node.js console application to create Azure Cosmos DB resources and query them.

In this tutorial, you will:

- Create and connect to an Azure Cosmos DB account.
- Set up your application.
- Create a database.
- Create a container.
- Add items to the container.
- Perform basic operations on the items, container, and database.

Prerequisites

Make sure you have the following resources:

- An active Azure account. If you don't have one, you can sign up for a Free Azure Trial.

  You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

- Node.js v6.0.0 or higher.

Create Azure Cosmos DB account

Let's create an Azure Cosmos DB account. If you already have an account you want to use, you can skip ahead to Set up your Node.js application. If you are using the Azure Cosmos DB Emulator, follow the steps at Azure Cosmos DB Emulator to set up the emulator and skip ahead to Set up your Node.js application.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.

SETTING	VALUE	DESCRIPTION
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

> **NOTE**
> You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

> **NOTE**
> The following options are not available if you select **Serverless** as the **Capacity mode**:
>
> - Apply Free Tier Discount
> - Geo-redundancy
> - Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Set up your Node.js application

Before you start writing code to build the application, you can build the framework for your app. Run the following steps to set up your Node.js application that has the framework code:

1. Open your favorite terminal.
2. Locate the folder or directory where you'd like to save your Node.js application.
3. Create empty JavaScript files with the following commands:
   - Windows:
     - `fsutil file createnew app.js 0`
     - `fsutil file createnew config.js 0`
     - `md data`
     - `fsutil file createnew data\databaseContext.js 0`
   - Linux/OS X:
     - `touch app.js`
     - `touch config.js`
     - `mkdir data`
     - `touch data/databaseContext.js`
4. Create and initialize a `package.json` file. Use the following command:
   - `npm init -y`
5. Install the @azure/cosmos module via npm. Use the following command:
   - `npm install @azure/cosmos --save`

Set your app's configurations

Now that your app exists, you need to make sure it can talk to Azure Cosmos DB. By updating a few configuration settings, as shown in the following steps, you can set your app to talk to Azure Cosmos DB:

1. Open the *config.js* file in your favorite text editor.
2. Copy and paste the following code snippet into the *config.js* file and set the properties `endpoint` and `key` to your Azure Cosmos DB endpoint URI and primary key. The database, container names are set to **Tasks**

and **Items**. The partition key you will use for this application is **/category**.

```
// @ts-check

const config = {
  endpoint: "<Your Azure Cosmos account URI>",
  key: "<Your Azure Cosmos account key>",
  databaseId: "Tasks",
  containerId: "Items",
  partitionKey: { kind: "Hash", paths: ["/category"] }
};

module.exports = config;
```

You can find the endpoint and key details in the **Keys** pane of the Azure portal.

The JavaScript SDK uses the generic terms *container* and *item*. A container can be a collection, graph, or table. An item can be a document, edge/vertex, or row, and is the content inside a container. In the previous code snippet, the `module.exports = config;` code is used to export the config object, so that you can reference it within the *app.js* file.

Create a database and a container

1. Open the *databaseContext.js* file in your favorite text editor.

2. Copy and paste the following code to the *databaseContext.js* file. This code defines a function that creates the "Tasks", "Items" database and the container if they don't already exist in your Azure Cosmos account:

```
const config = require("../config");
const CosmosClient = require("@azure/cosmos").CosmosClient;

/*
// This script ensures that the database is setup and populated correctly
*/
async function create(client, databaseId, containerId) {
  const partitionKey = config.partitionKey;

  /**
   * Create the database if it does not exist
   */
  const { database } = await client.databases.createIfNotExists({
    id: databaseId
  });
  console.log(`Created database:\n${database.id}\n`);

  /**
   * Create the container if it does not exist
   */
  const { container } = await client
    .database(databaseId)
    .containers.createIfNotExists(
      { id: containerId, partitionKey },
      { offerThroughput: 400 }
    );

  console.log(`Created container:\n${container.id}\n`);
}

module.exports = { create };
```

A database is the logical container of items partitioned across containers. You create a database by using either the `createIfNotExists` or create function of the **Databases** class. A container consists of items which in the case of the SQL API is JSON documents. You create a container by using either the `createIfNotExists` or create function from the **Containers** class. After creating a container, you can store and query the data.

> **WARNING**
>
> Creating a container has pricing implications. Visit our pricing page so you know what to expect.

Import the configuration

1. Open the *app.js* file in your favorite text editor.
2. Copy and paste the code below to import the `@azure/cosmos` module, the configuration, and the databaseContext that you defined in the previous steps.

```
const CosmosClient = require("@azure/cosmos").CosmosClient;
const config = require("./config");
const dbContext = require("./data/databaseContext");
```

Connect to the Azure Cosmos account

In the *app.js* file, copy and paste the following code to use the previously saved endpoint and key to create a new CosmosClient object.

```
const { endpoint, key, databaseId, containerId } = config;

const client = new CosmosClient({ endpoint, key });

const database = client.database(databaseId);
const container = database.container(containerId);

// Make sure Tasks database is already setup. If not, create it.
await dbContext.create(client, databaseId, containerId);
```

NOTE

If connecting to the **Cosmos DB Emulator**, disable TLS verification for your node process:

```
process.env.NODE_TLS_REJECT_UNAUTHORIZED = "0";
const client = new CosmosClient({ endpoint, key });
```

Now that you have the code to initialize the Azure Cosmos DB client, let's take a look at how to work with Azure Cosmos DB resources.

Query items

Azure Cosmos DB supports rich queries against JSON items stored in each container. The following sample code shows a query that you can run against the items in your container.You can query the items by using the query function of the `Items` class. Add the following code to the *app.js* file to query the items from your Azure Cosmos account:

```
console.log(`Querying container: Items`);

// query to return all items
const querySpec = {
  query: "SELECT * from c"
};

// read all items in the Items container
const { resources: items } = await container.items
  .query(querySpec)
  .fetchAll();

items.forEach(item => {
  console.log(`${item.id} - ${item.description}`);
});
```

Create an item

An item can be created by using the create function of the `Items` class. When you're using the SQL API, items are projected as documents, which are user-defined (arbitrary) JSON content. In this tutorial, you create a new item within the tasks database.

1. In the app.js file, define the item definition:

```
const newItem = {
  id: "3",
  category: "fun",
  name: "Cosmos DB",
  description: "Complete Cosmos DB Node.js Quickstart ⚡",
  isComplete: false
};
```

2. Add the following code to create the previously defined item:

```
/** Create new item
 * newItem is defined at the top of this file
 */
const { resource: createdItem } = await container.items.create(newItem);

console.log(`\r\nCreated new item: ${createdItem.id} - ${createdItem.description}\r\n`);
```

Update an item

Azure Cosmos DB supports replacing the contents of items. Copy and paste the following code to *app.js* file. This code gets an item from the container and updates the *isComplete* field to true.

```
/** Update item
 * Pull the id and partition key value from the newly created item.
 * Update the isComplete field to true.
 */
const { id, category } = createdItem;

createdItem.isComplete = true;

const { resource: updatedItem } = await container
  .item(id, category)
  .replace(createdItem);

console.log(`Updated item: ${updatedItem.id} - ${updatedItem.description}`);
console.log(`Updated isComplete to ${updatedItem.isComplete}\r\n`);
```

Delete an item

Azure Cosmos DB supports deleting JSON items. The following code shows how to get an item by its ID and delete it. Copy and paste the following code to *app.js* file:

```
/**
 * Delete item
 * Pass the id and partition key value to delete the item
 */
const { resource: result } = await container.item(id, category).delete();
console.log(`Deleted item with id: ${id}`);
```

Run your Node.js application

Altogether, your code should look like this:

```
// @ts-check
//  <ImportConfiguration>
const CosmosClient = require("@azure/cosmos").CosmosClient;
const config = require("./config");
```

```
const dbContext = require("./data/databaseContext");
//  </ImportConfiguration>

//  <DefineNewItem>
const newItem = {
  id: "3",
  category: "fun",
  name: "Cosmos DB",
  description: "Complete Cosmos DB Node.js Quickstart ⚡",
  isComplete: false
};
//  </DefineNewItem>

async function main() {

  // <CreateClientObjectDatabaseContainer>
  const { endpoint, key, databaseId, containerId } = config;

  const client = new CosmosClient({ endpoint, key });

  const database = client.database(databaseId);
  const container = database.container(containerId);

  // Make sure Tasks database is already setup. If not, create it.
  await dbContext.create(client, databaseId, containerId);
  // </CreateClientObjectDatabaseContainer>

  try {
    // <QueryItems>
    console.log(`Querying container: Items`);

    // query to return all items
    const querySpec = {
      query: "SELECT * from c"
    };

    // read all items in the Items container
    const { resources: items } = await container.items
      .query(querySpec)
      .fetchAll();

    items.forEach(item => {
      console.log(`${item.id} - ${item.description}`);
    });
    // </QueryItems>

    // <CreateItem>
    /** Create new item
     * newItem is defined at the top of this file
     */
    const { resource: createdItem } = await container.items.create(newItem);

    console.log(`\r\nCreated new item: ${createdItem.id} - ${createdItem.description}\r\n`);
    // </CreateItem>

    // <UpdateItem>
    /** Update item
     * Pull the id and partition key value from the newly created item.
     * Update the isComplete field to true.
     */
    const { id, category } = createdItem;

    createdItem.isComplete = true;

    const { resource: updatedItem } = await container
      .item(id, category)
      .replace(createdItem);

    console.log(`Updated item: ${updatedItem.id} - ${updatedItem.description}`);
```

```
    console.log(`Updated item: ${updatedItem.id} - ${updatedItem.description}`);
    console.log(`Updated isComplete to ${updatedItem.isComplete}\r\n`);
    // </UpdateItem>

    // <DeleteItem>
    /**
     * Delete item
     * Pass the id and partition key value to delete the item
     */
    const { resource: result } = await container.item(id, category).delete();
    console.log(`Deleted item with id: ${id}`);
    // </DeleteItem>

  } catch (err) {
    console.log(err.message);
  }
}

main();
```

In your terminal, locate your `app.js` file and run the command:

```
node app.js
```

You should see the output of your get started app. The output should match the example text below.

```
Created database:
Tasks

Created container:
Items

Querying container: Items
1 - Pick up apples and strawberries.

Created new item: 3 - Complete Cosmos DB Node.js Quickstart ▯

Updated item: 3 - Complete Cosmos DB Node.js Quickstart ▯
Updated isComplete to true

Deleted item with id: 3
```

Get the complete Node.js tutorial solution

If you didn't have time to complete the steps in this tutorial, or just want to download the code, you can get it from GitHub.

To run the getting started solution that contains all the code in this article, you will need:

- An Azure Cosmos DB account.
- The Getting Started solution available on GitHub.

Install the project's dependencies via npm. Use the following command:

- `npm install`

Next, in the `config.js` file, update the config.endpoint and config.key values as described in Step 3: Set your app's configurations.

Then in your terminal, locate your `app.js` file and run the command:

```
node app.js
```

Clean up resources

When these resources are no longer needed, you can delete the resource group, Azure Cosmos DB account, and all the related resources. To do so, select the resource group that you used for the Azure Cosmos DB account, select **Delete**, and then confirm the name of the resource group to delete.

Monitor an Azure Cosmos DB account

Tutorial: Develop an ASP.NET Core MVC web application with Azure Cosmos DB by using .NET SDK

12/4/2020 • 17 minutes to read • Edit Online

APPLIES TO: SQL API

This tutorial shows you how to use Azure Cosmos DB to store and access data from an ASP.NET MVC application that is hosted on Azure. In this tutorial, you use the .NET SDK V3. The following image shows the web page that you'll build by using the sample in this article:

If you don't have time to complete the tutorial, you can download the complete sample project from GitHub.

This tutorial covers:

- Creating an Azure Cosmos account
- Creating an ASP.NET Core MVC app
- Connecting the app to Azure Cosmos DB
- Performing create, read, update, and delete (CRUD) operations on the data

> **TIP**
> This tutorial assumes that you have prior experience using ASP.NET Core MVC and Azure App Service. If you are new to ASP.NET Core or the prerequisite tools, we recommend you to download the complete sample project from GitHub, add the required NuGet packages, and run it. Once you build the project, you can review this article to gain insight on the code in the context of the project.

Prerequisites

Before following the instructions in this article, make sure that you have the following resources:

- An active Azure account. If you don't have an Azure subscription, create a free account before you begin.

  You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

- Visual Studio 2019. Download and use the free Visual Studio 2019 Community Edition. Make sure that you enable the **Azure development** workload during the Visual Studio setup.

All the screenshots in this article are from Microsoft Visual Studio Community 2019. If you use a different version, your screens and options may not match entirely. The solution should work if you meet the prerequisites.

Step 1: Create an Azure Cosmos account

Let's start by creating an Azure Cosmos account. If you already have an Azure Cosmos DB SQL API account or if you're using the Azure Cosmos DB Emulator, skip to Step 2: Create a new ASP.NET MVC application.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.

SETTING	VALUE	DESCRIPTION
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Go to the Azure Cosmos DB account page, and select **Keys**. Copy the values to use in the web application you create next.

In the next section, you create a new ASP.NET Core MVC application.

Step 2: Create a new ASP.NET Core MVC application

1. Open Visual Studio and select **Create a new project**.

2. In **Create a new project**, find and select **ASP.NET Core Web Application** for C#. Select **Next** to continue.

3. In **Configure your new project**, name the project *todo* and select **Create**.

4. In **Create a new ASP.NET Core Web Application**, choose **Web Application (Model-View-Controller)**. Select **Create** to continue.

   Visual Studio creates an empty MVC application.

5. Select **Debug** > **Start Debugging** or F5 to run your ASP.NET application locally.

Step 3: Add Azure Cosmos DB NuGet package to the project

Now that we have most of the ASP.NET Core MVC framework code that we need for this solution, let's add the NuGet packages required to connect to Azure Cosmos DB.

1. In **Solution Explorer**, right-click your project and select **Manage NuGet Packages**.

2. In the **NuGet Package Manager**, search for and select **Microsoft.Azure.Cosmos**. Select **Install**.

   Visual Studio downloads and installs the Azure Cosmos DB package and its dependencies.

   You can also use **Package Manager Console** to install the NuGet package. To do so, select **Tools** > **NuGet Package Manager** > **Package Manager Console**. At the prompt, type the following command:

```
Install-Package Microsoft.Azure.Cosmos
```

Step 4: Set up the ASP.NET Core MVC application

Now let's add the models, the views, and the controllers to this MVC application.

Add a model

1. In **Solution Explorer**, right-click the **Models** folder, select **Add** > **Class**.
2. In **Add New Item**, name your new class *Item.cs* and select **Add**.
3. Replace the contents of *Item.cs* class with the following code:

```
namespace todo.Models
{
    using Newtonsoft.Json;

    public class Item
    {
        [JsonProperty(PropertyName = "id")]
        public string Id { get; set; }

        [JsonProperty(PropertyName = "name")]
        public string Name { get; set; }

        [JsonProperty(PropertyName = "description")]
        public string Description { get; set; }

        [JsonProperty(PropertyName = "isComplete")]
        public bool Completed { get; set; }
    }
}
```

Azure Cosmos DB uses JSON to move and store data. You can use the `JsonProperty` attribute to control how JSON serializes and deserializes objects. The `Item` class demonstrates the `JsonProperty` attribute. This code controls the format of the property name that goes into JSON. It also renames the .NET property `Completed`.

Add views

Next, let's add the following views.

- A create item view
- A delete item view
- A view to get an item details
- An edit item view
- A view to list all the items

Create item view

1. In **Solution Explorer**, right-click the **Views** folder and select **Add** > **New Folder**. Name the folder *Item*.
2. Right-click the empty **Item** folder, then select **Add** > **View**.
3. In **Add MVC View**, make the following changes:
   - In **View name**, enter *Create*.
   - In **Template**, select **Create**.
   - In **Model class**, select **Item (todo.Models)**.
   - Select **Use a layout page** and enter *~/Views/Shared/_Layout.cshtml*.

- Select **Add**.

4. Next select **Add** and let Visual Studio create a new template view. Replace the code in the generated file with the following contents:

```
@model todo.Models.Item

@{
    ViewBag.Title = "Create";
    Layout = "~/Views/Shared/_Layout.cshtml";
}

<h2>Create a new To-Do Item</h2>

@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()

    <div class="form-horizontal">
        <hr />
        @Html.ValidationSummary(true, "", new { @class = "text-danger" })
        <div class="form-group">
            @Html.LabelFor(model => model.Name, htmlAttributes: new { @class = "control-label col-md-2"
})
            <div class="col-md-10">
                @Html.EditorFor(model => model.Name, new { htmlAttributes = new { @class = "form-
control" } })
                @Html.ValidationMessageFor(model => model.Name, "", new { @class = "text-danger" })
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Description, htmlAttributes: new { @class = "control-label
col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Description, new { htmlAttributes = new { @class =
"form-control" } })
                @Html.ValidationMessageFor(model => model.Description, "", new { @class = "text-danger"
})
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Completed, htmlAttributes: new { @class = "control-label col-
md-2" })
            <div class="col-md-10">
                <div class="checkbox">
                    @Html.EditorFor(model => model.Completed)
                    @Html.ValidationMessageFor(model => model.Completed, "", new { @class = "text-
danger" })
                </div>
            </div>
        </div>

        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </div>
    </div>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>
<script src="~/bundles/jqueryval"></script>
```

Delete item view

1. From the **Solution Explorer**, right-click the **Item** folder again, select **Add** > **View**.

2. In **Add MVC View**, make the following changes:
   - In the **View name** box, type *Delete*.
   - In the **Template** box, select **Delete**.
   - In the **Model class** box, select **Item (todo.Models)**.
   - Select **Use a layout page** and enter *~/Views/Shared/_Layout.cshtml*.
   - Select **Add**.
3. Next select **Add** and let Visual Studio create a new template view. Replace the code in the generated file with the following contents:

```
@model todo.Models.Item

@{
    ViewBag.Title = "Delete";
    Layout = "~/Views/Shared/_Layout.cshtml";
}

<h2>Delete a To-Do Item</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Name)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Name)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.Description)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Description)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.Completed)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Completed)
        </dd>
    </dl>

    @using (Html.BeginForm()) {
        @Html.AntiForgeryToken()

        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            @Html.ActionLink("Back to List", "Index")
        </div>
    }
</div>
```

Add a view to get an item details

1. In **Solution Explorer**, right-click the **Item** folder again, select **Add** > **View**.
2. In **Add MVC View**, provide the following values:

- In **View name**, enter *Details*.
- In **Template**, select **Details**.
- In **Model class**, select **Item (todo.Models)**.
- Select **Use a layout page** and enter *~/Views/Shared/_Layout.cshtml*.

3. Next select **Add** and let Visual Studio create a new template view. Replace the code in the generated file with the following contents:

```
@model todo.Models.Item

<h2>View To-Do Item Details</h2>

<div>
    <h4>Item</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Name)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Name)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.Description)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Description)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.Completed)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Completed)
        </dd>

    </dl>
</div>
<p>
    @Html.ActionLink("Edit", "Edit", new { id = Model.Id }) |
    @Html.ActionLink("Back to List", "Index")
</p>
```

Add an edit item view

1. From the **Solution Explorer**, right-click the **Item** folder again, select **Add** > **View**.

2. In **Add MVC View**, make the following changes:

   - In the **View name** box, type *Edit*.
   - In the **Template** box, select **Edit**.
   - In the **Model class** box, select **Item (todo.Models)**.
   - Select **Use a layout page** and enter *~/Views/Shared/_Layout.cshtml*.
   - Select **Add**.

3. Next select **Add** and let Visual Studio create a new template view. Replace the code in the generated file with the following contents:

```
@model todo.Models.Item

<h2>Edit a To-Do Item</h2>

@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()

    <div class="form-horizontal">
        <h4>Item</h4>
        <hr />
        @Html.ValidationSummary(true, "", new { @class = "text-danger" })
        @Html.HiddenFor(model => model.Id)

        <div class="form-group">
            @Html.LabelFor(model => model.Name, htmlAttributes: new { @class = "control-label col-md-2"
})
            <div class="col-md-10">
                @Html.EditorFor(model => model.Name, new { htmlAttributes = new { @class = "form-
control" } })
                @Html.ValidationMessageFor(model => model.Name, "", new { @class = "text-danger" })
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Description, htmlAttributes: new { @class = "control-label
col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Description, new { htmlAttributes = new { @class =
"form-control" } })
                @Html.ValidationMessageFor(model => model.Description, "", new { @class = "text-danger"
})
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Completed, htmlAttributes: new { @class = "control-label col-
md-2" })
            <div class="col-md-10">
                <div class="checkbox">
                    @Html.EditorFor(model => model.Completed)
                    @Html.ValidationMessageFor(model => model.Completed, "", new { @class = "text-
danger" })
                </div>
            </div>
        </div>

        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>

<script src="~/bundles/jqueryval"></script>
```

Add a view to list all the items

And finally, add a view to get all the items with the following steps:

1. From the **Solution Explorer**, right-click the **Item** folder again, select **Add** > **View**.

2. In **Add MVC View**, make the following changes:
   - In the **View name** box, type *Index*.
   - In the **Template** box, select **List**.
   - In the **Model class** box, select **Item (todo.Models)**.
   - Select **Use a layout page** and enter *~/Views/Shared/_Layout.cshtml*.
   - Select **Add**.
3. Next select **Add** and let Visual Studio create a new template view. Replace the code in the generated file with the following contents:

```
@model IEnumerable<todo.Models.Item>

@{
    ViewBag.Title = "List of To-Do Items";
    Layout = "~/Views/Shared/_Layout.cshtml";
}

<h2>List of To-Do Items</h2>

<table class="table">
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.Name)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Description)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Completed)
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Description)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Completed)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.Id }) |
            @Html.ActionLink("Details", "Details", new { id=item.Id }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.Id })
        </td>
    </tr>
}

</table>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
```

Once you complete these steps, close all the *cshtml* documents in Visual Studio.

Declare and initialize services

First, we'll add a class that contains the logic to connect to and use Azure Cosmos DB. For this tutorial, we'll

encapsulate this logic into a class called `CosmosDbService` and an interface called `ICosmosDbService`. This service does the CRUD operations. It also does read feed operations such as listing incomplete items, creating, editing, and deleting the items.

1. In **Solution Explorer**, right-click your project and select **Add** > **New Folder**. Name the folder *Services*.
2. Right-click the **Services** folder, select **Add** > **Class**. Name the new class *CosmosDbService* and select **Add**.
3. Replace the contents of *CosmosDbService.cs* with the following code:

```
namespace todo
{
    using System.Collections.Generic;
    using System.Linq;
    using System.Threading.Tasks;
    using todo.Models;
    using Microsoft.Azure.Cosmos;
    using Microsoft.Azure.Cosmos.Fluent;
    using Microsoft.Extensions.Configuration;

    public class CosmosDbService : ICosmosDbService
    {
        private Container _container;

        public CosmosDbService(
            CosmosClient dbClient,
            string databaseName,
            string containerName)
        {
            this._container = dbClient.GetContainer(databaseName, containerName);
        }

        public async Task AddItemAsync(Item item)
        {
            await this._container.CreateItemAsync<Item>(item, new PartitionKey(item.Id));
        }

        public async Task DeleteItemAsync(string id)
        {
            await this._container.DeleteItemAsync<Item>(id, new PartitionKey(id));
        }

        public async Task<Item> GetItemAsync(string id)
        {
            try
            {
                ItemResponse<Item> response = await this._container.ReadItemAsync<Item>(id, new
PartitionKey(id));
                return response.Resource;
            }
            catch(CosmosException ex) when (ex.StatusCode == System.Net.HttpStatusCode.NotFound)
            {
                return null;
            }

        }

        public async Task<IEnumerable<Item>> GetItemsAsync(string queryString)
        {
            var query = this._container.GetItemQueryIterator<Item>(new QueryDefinition(queryString));
            List<Item> results = new List<Item>();
            while (query.HasMoreResults)
            {
                var response = await query.ReadNextAsync();

                results.AddRange(response.ToList());
            }
```

```
            return results;
        }

        public async Task UpdateItemAsync(string id, Item item)
        {
            await this._container.UpsertItemAsync<Item>(item, new PartitionKey(id));
        }
    }
}
```

4. Right-click the **Services** folder, select **Add** > **Class**. Name the new class *ICosmosDbService* and select **Add**.

5. Add the following code to *ICosmosDbService* class:

```
namespace todo
{
    using System.Collections.Generic;
    using System.Threading.Tasks;
    using todo.Models;

    public interface ICosmosDbService
    {
        Task<IEnumerable<Item>> GetItemsAsync(string query);
        Task<Item> GetItemAsync(string id);
        Task AddItemAsync(Item item);
        Task UpdateItemAsync(string id, Item item);
        Task DeleteItemAsync(string id);
    }
}
```

6. Open the *Startup.cs* file in your solution and add the following method **InitializeCosmosClientInstanceAsync**, which reads the configuration and initializes the client.

```
/// <summary>
/// Creates a Cosmos DB database and a container with the specified partition key.
/// </summary>
/// <returns></returns>
private static async Task<CosmosDbService> InitializeCosmosClientInstanceAsync(IConfigurationSection
configurationSection)
{
    string databaseName = configurationSection.GetSection("DatabaseName").Value;
    string containerName = configurationSection.GetSection("ContainerName").Value;
    string account = configurationSection.GetSection("Account").Value;
    string key = configurationSection.GetSection("Key").Value;
    Microsoft.Azure.Cosmos.CosmosClient client = new Microsoft.Azure.Cosmos.CosmosClient(account, key);
    CosmosDbService cosmosDbService = new CosmosDbService(client, databaseName, containerName);
    Microsoft.Azure.Cosmos.DatabaseResponse database = await
client.CreateDatabaseIfNotExistsAsync(databaseName);
    await database.Database.CreateContainerIfNotExistsAsync(containerName, "/id");

    return cosmosDbService;
}
```

7. On that same file, replace the `ConfigureServices` method with:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddSingleton<ICosmosDbService>
(InitializeCosmosClientInstanceAsync(Configuration.GetSection("CosmosDb")).GetAwaiter().GetResult());
}
```

The code in this step initializes the client based on the configuration as a singleton instance to be injected through Dependency injection in ASP.NET Core.

And make sure to change the default MVC Controller to `Item` by editing the routes in the `Configure` method of the same file:

```
 app.UseEndpoints(endpoints =>
       {
             endpoints.MapControllerRoute(
                name: "default",
                pattern: "{controller=Item}/{action=Index}/{id?}");
       });
```

8. Define the configuration in the project's *appsettings.json* file as shown in the following snippet:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*",
  "CosmosDb": {
    "Account": "<Endpoint URI of your Azure Cosmos account>",
    "Key": "<PRIMARY KEY of your Azure Cosmos account>",
    "DatabaseName": "Tasks",
    "ContainerName": "Item"
  }
}
```

Add a controller

1. In **Solution Explorer**, right-click the **Controllers** folder, select **Add** > **Controller**.

2. In **Add Scaffold**, select **MVC Controller - Empty** and select **Add**.

3. Name your new controller *ItemController*.

4. Replace the contents of *ItemController.cs* with the following code:

```
namespace todo.Controllers
{
    using System;
    using System.Threading.Tasks;
    using Microsoft.AspNetCore.Mvc;
    using todo.Models;

    public class ItemController : Controller
    {
        private readonly ICosmosDbService _cosmosDbService;
        public ItemController(ICosmosDbService cosmosDbService)
        {
            _cosmosDbService = cosmosDbService;
        }

        [ActionName("Index")]
        public async Task<IActionResult> Index()
        {
            return View(await _cosmosDbService.GetItemsAsync("SELECT * FROM c"));
        }

        [ActionName("Create")]
        public IActionResult Create()
        {
            return View();
        }

        [HttpPost]
        [ActionName("Create")]
        [ValidateAntiForgeryToken]
        public async Task<ActionResult> CreateAsync([Bind("Id,Name,Description,Completed")] Item item)
        {
            if (ModelState.IsValid)
            {
                item.Id = Guid.NewGuid().ToString();
```

```
            await _cosmosDbService.AddItemAsync(item);
            return RedirectToAction("Index");
        }

        return View(item);
    }

    [HttpPost]
    [ActionName("Edit")]
    [ValidateAntiForgeryToken]
    public async Task<ActionResult> EditAsync([Bind("Id,Name,Description,Completed")] Item item)
    {
        if (ModelState.IsValid)
        {
            await _cosmosDbService.UpdateItemAsync(item.Id, item);
            return RedirectToAction("Index");
        }

        return View(item);
    }

    [ActionName("Edit")]
    public async Task<ActionResult> EditAsync(string id)
    {
        if (id == null)
        {
            return BadRequest();
        }

        Item item = await _cosmosDbService.GetItemAsync(id);
        if (item == null)
        {
            return NotFound();
        }

        return View(item);
    }

    [ActionName("Delete")]
    public async Task<ActionResult> DeleteAsync(string id)
    {
        if (id == null)
        {
            return BadRequest();
        }

        Item item = await _cosmosDbService.GetItemAsync(id);
        if (item == null)
        {
            return NotFound();
        }

        return View(item);
    }

    [HttpPost]
    [ActionName("Delete")]
    [ValidateAntiForgeryToken]
    public async Task<ActionResult> DeleteConfirmedAsync([Bind("Id")] string id)
    {
        await _cosmosDbService.DeleteItemAsync(id);
        return RedirectToAction("Index");
    }

    [ActionName("Details")]
    public async Task<ActionResult> DetailsAsync(string id)
    {
        return View(await _cosmosDbService.GetItemAsync(id));
    }
```

```
    }
}
```

The **ValidateAntiForgeryToken** attribute is used here to help protect this application against cross-site request forgery attacks. Your views should work with this anti-forgery token as well. For more information and examples, see Preventing Cross-Site Request Forgery (CSRF) Attacks in ASP.NET MVC Application. The source code provided on GitHub has the full implementation in place.

We also use the **Bind** attribute on the method parameter to help protect against over-posting attacks. For more information, see Tutorial: Implement CRUD Functionality with the Entity Framework in ASP.NET MVC.

Step 5: Run the application locally

To test the application on your local computer, use the following steps:

1. Press F5 in Visual Studio to build the application in debug mode. It should build the application and launch a browser with the empty grid page we saw before:

   If the application instead opens to the home page, append `/Item` to the url.

2. Select the **Create New** link and add values to the **Name** and **Description** fields. Leave the **Completed** check box unselected. If you select it, the app adds the new item in a completed state. The item no longer appears on the initial list.

3. Select **Create**. The app sends you back to the **Index** view, and your item appears in the list. You can add a few more items to your **To-Do** list.

4. Select **Edit** next to an **Item** on the list. The app opens the **Edit** view where you can update any property of your object, including the **Completed** flag. If you select **Completed** and select **Save**, the app displays the **Item** as completed in the list.

5. Verify the state of the data in the Azure Cosmos DB service using Cosmos Explorer or the Azure Cosmos DB Emulator's Data Explorer.

6. Once you've tested the app, select Ctrl+F5 to stop debugging the app. You're ready to deploy!

Step 6: Deploy the application

Now that you have the complete application working correctly with Azure Cosmos DB we're going to deploy this web app to Azure App Service.

1. To publish this application, right-click the project in **Solution Explorer** and select **Publish**.

2. In **Pick a publish target**, select **App Service**.

3. To use an existing App Service profile, choose **Select Existing**, then select **Publish**.

4. In **App Service**, select a **Subscription**. Use the **View** filter to sort by resource group or resource type.

5. Find your profile, and then select **OK**. Next search the required Azure App Service and select **OK**.

Another option is to create a new profile:

1. As in the previous procedure, right-click the project in **Solution Explorer** and select **Publish**.
2. In **Pick a publish target**, select **App Service**.
3. In **Pick a publish target**, select **Create New** and select **Publish**.
4. In **App Service**, enter your Web App name and the appropriate subscription, resource group, and hosting plan, then select **Create**.

In a few seconds, Visual Studio publishes your web application and launches a browser where you can see your project running in Azure!

Next steps

In this tutorial, you've learned how to build an ASP.NET Core MVC web application. Your application can access data stored in Azure Cosmos DB. You can now continue with these resources:

- Partitioning in Azure Cosmos DB
- Getting started with SQL queries
- How to model and partition data on Azure Cosmos DB using a real-world example

Tutorial: Build a Java web application using Azure Cosmos DB and the SQL API

12/4/2020 • 23 minutes to read • Edit Online

APPLIES TO: SQL API

This Java web application tutorial shows you how to use the Microsoft Azure Cosmos DB service to store and access data from a Java application hosted on Azure App Service Web Apps. In this article, you will learn:

- How to build a basic JavaServer Pages (JSP) application in Eclipse.
- How to work with the Azure Cosmos DB service using the Azure Cosmos DB Java SDK.

This Java application tutorial shows you how to create a web-based task-management application that enables you to create, retrieve, and mark tasks as complete, as shown in the following image. Each of the tasks in the ToDo list is stored as JSON documents in Azure Cosmos DB.

> **TIP**
> This application development tutorial assumes that you have prior experience using Java. If you are new to Java or the prerequisite tools, we recommend downloading the complete todo project from GitHub and building it using the instructions at the end of this article. Once you have it built, you can review the article to gain insight on the code in the context of the project.

Prerequisites for this Java web application tutorial

Before you begin this application development tutorial, you must have the following:

- If you don't have an Azure subscription, create a free account before you begin.

  You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

- Java Development Kit (JDK) 7+.
- Eclipse IDE for Java EE Developers.
- An Azure Web Site with a Java runtime environment (e.g. Tomcat or Jetty) enabled.

If you're installing these tools for the first time, coreservlets.com provides a walk-through of the installation process in the quickstart section of their Tutorial: Installing TomCat7 and Using it with Eclipse article.

Create an Azure Cosmos DB account

Let's start by creating an Azure Cosmos DB account. If you already have an account or if you are using the Azure Cosmos DB Emulator for this tutorial, you can skip to Step 2: Create the Java JSP application.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.

SETTING	VALUE	DESCRIPTION
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Go to the Azure Cosmos DB account page, and select **Keys**. Copy the values to use in the web application you create next.

Create the Java JSP application

To create the JSP application:

1. First, we'll start off by creating a Java project. Start Eclipse, then click **File**, click **New**, and then click **Dynamic Web Project**. If you don't see **Dynamic Web Project** listed as an available project, do the following: click **File**, click **New**, click **Project**..., expand **Web**, click **Dynamic Web Project**, and click **Next**.

2. Enter a project name in the **Project name** box, and in the **Target Runtime** drop-down menu, optionally select a value (e.g. Apache Tomcat v7.0), and then click **Finish**. Selecting a target runtime enables you to run your project locally through Eclipse.

3. In Eclipse, in the Project Explorer view, expand your project. Right-click **WebContent**, click **New**, and then click **JSP File**.

4. In the **New JSP File** dialog box, name the file **index.jsp**. Keep the parent folder as **WebContent**, as shown in the following illustration, and then click **Next**.

5. In the **Select JSP Template** dialog box, for the purpose of this tutorial select **New JSP File (html)**, and then click **Finish**.

6. When the *index.jsp* file opens in Eclipse, add text to display **Hello World!** within the existing `<body>` element. The updated `<body>` content should look like the following code:

```
<body>
  <% out.println("Hello World!"); %>
</body>
```

7. Save the *index.jsp* file.

8. If you set a target runtime in step 2, you can click **Project** and then **Run** to run your JSP application locally:

Install the SQL Java SDK

The easiest way to pull in the SQL Java SDK and its dependencies is through Apache Maven. To do this, you need to convert your project to a Maven project by using the following steps:

1. Right-click your project in the Project Explorer, click **Configure**, click **Convert to Maven Project**.

2. In the **Create new POM** window, accept the defaults, and click **Finish**.

3. In **Project Explorer**, open the pom.xml file.

4. On the **Dependencies** tab, in the **Dependencies** pane, click **Add**.

5. In the **Select Dependency** window, do the following:

   - In the **Group Id** box, enter `com.azure`.

- In the **Artifact Id** box, enter `azure-cosmos`.
- In the **Version** box, enter `4.0.1-beta.1`.

Or, you can add the dependency XML for Group ID and Artifact ID directly to the *pom.xml* file:

```
<dependency>
   <groupId>com.azure</groupId>
   <artifactId>azure-cosmos</artifactId>
   <version>4.0.1-beta.1</version>
</dependency>
```

6. Click **OK** and Maven will install the SQL Java SDK or save the pom.xml file.

Use the Azure Cosmos DB service in your Java application

Now let's add the models, the views, and the controllers to your web application.

Add a model

First, let's define a model within a new file *TodoItem.java*. The `TodoItem` class defines the schema of an item along with the getter and setter methods:

```
package com.microsoft.azure.documentdb.sample.model;

//@Data
//@Builder
public class TodoItem {
    private String entityType;
    private String category;
    private boolean complete;
    private String id;
    private String name;

    public String getCategory() {
        return category;
    }

    public void setCategory(String category) {
        this.category = category;
    }

    public String getEntityType() {
        return entityType;
    }

    public void setEntityType(String entityType) {
        this.entityType = entityType;
    }

    public boolean isComplete() {
        return complete;
    }

    public void setComplete(boolean complete) {
        this.complete = complete;
    }

    public String getId() {
        return id;
    }

    public void setId(String id) {
        this.id = id;
    }

    public String getName() {
        return name;
    }

    public void setName(String name) {
        this.name = name;
    }

}
```

Add the Data Access Object(DAO) classes

Create a Data Access Object (DAO) to abstract persisting the ToDo items to Azure Cosmos DB. In order to save ToDo items to a collection, the client needs to know which database and collection to persist to (as referenced by self-links). In general, it is best to cache the database and collection when possible to avoid additional round-trips to the database.

1. To invoke the Azure Cosmos DB service, you must instantiate a new `cosmosClient` object. In general, it is best to reuse the `cosmosClient` object rather than constructing a new client for each subsequent request. You can reuse the client by defining it within the `cosmosClientFactory` class. Update the HOST and MASTER_KEY values that you saved in step 1. Replace the HOST variable with with your URI and replace the

MASTER_KEY with your PRIMARY KEY. Use the following code to create the `CosmosClientFactory` class within the *CosmosClientFactory.java* file:

```
package com.microsoft.azure.documentdb.sample.dao;

import com.azure.cosmos.ConnectionPolicy;
import com.azure.cosmos.ConsistencyLevel;
import com.azure.cosmos.CosmosClient;
import com.azure.cosmos.CosmosClientBuilder;

public class CosmosClientFactory {
    private static final String HOST = "https://docdb-java-sample.documents.azure.com:443/";
    private static final String MASTER_KEY = "[YOUR_KEY_HERE]";

    private static CosmosClient cosmosClient = new CosmosClientBuilder()
            .setEndpoint(HOST)
            .setKey(MASTER_KEY)
            .setConnectionPolicy(ConnectionPolicy.getDefaultPolicy())
            .setConsistencyLevel(ConsistencyLevel.EVENTUAL)
            .buildClient();

    public static CosmosClient getCosmosClient() {
        return cosmosClient;
    }

}
```

2. Create a new *TodoDao.java* file and add the `TodoDao` class to create, update, read, and delete the todo items:

```
package com.microsoft.azure.documentdb.sample.dao;

import java.util.List;

import com.microsoft.azure.documentdb.sample.model.TodoItem;

public interface TodoDao {
    /**
     * @return A list of TodoItems
     */
    public List<TodoItem> readTodoItems();

    /**
     * @param todoItem
     * @return whether the todoItem was persisted.
     */
    public TodoItem createTodoItem(TodoItem todoItem);

    /**
     * @param id
     * @return the TodoItem
     */
    public TodoItem readTodoItem(String id);

    /**
     * @param id
     * @return the TodoItem
     */
    public TodoItem updateTodoItem(String id, boolean isComplete);

    /**
     *
     * @param id
     * @return whether the delete was successful.
     */
    public boolean deleteTodoItem(String id);
}
```

3. Create a new *MockDao.java* file and add the `MockDao` class, this class implements the `TodoDao` class to perform CRUD operations on the items:

```
package com.microsoft.azure.documentdb.sample.dao;

import java.util.ArrayList;
import java.util.HashMap;
import java.util.List;
import java.util.Map;

import lombok.NonNull;

import org.apache.commons.lang3.StringUtils;

import com.microsoft.azure.documentdb.sample.model.TodoItem;

public class MockDao implements TodoDao {
    private final Map<String, TodoItem> todoItemMap;

    public MockDao() {
        todoItemMap = new HashMap<String, TodoItem>();
    }

    @Override
    public TodoItem createTodoItem(@NonNull TodoItem todoItem) {
        if (StringUtils.isEmpty(todoItem.getId())) {
            todoItem.setId(generateId());
        }
        todoItemMap.put(todoItem.getId(), todoItem);
        return todoItem;
    }

    @Override
    public TodoItem readTodoItem(@NonNull String id) {
        return todoItemMap.get(id);
    }

    @Override
    public List<TodoItem> readTodoItems() {
        return new ArrayList<TodoItem>(todoItemMap.values());
    }

    @Override
    public TodoItem updateTodoItem(String id, boolean isComplete) {
        todoItemMap.get(id).setComplete(isComplete);
        return todoItemMap.get(id);
    }

    @Override
    public boolean deleteTodoItem(@NonNull String id) {
        todoItemMap.remove(id);
        return true;
    }

    private String generateId() {
        return new Integer(todoItemMap.size()).toString();
    }
}
```

4. Create a new *DocDbDao.java* file and add the `DocDbDao` class. This class defines code to persist the TodoItems into the container, retrieves your database and collection, if it exists, or create a new one if it doesn't exist. This example uses Gson to serialize and de-serialize the TodoItem Plain Old Java Objects (POJOs) to JSON documents. In order to save ToDo items to a collection, the client needs to know which database and collection to persist to (as referenced by self-links). This class also defines helper function to retrieve the documents by another attribute (e.g. "ID") rather than self-link. You can use the helper method to retrieve a TodoItem JSON document by ID and then deserialize it to a POJO.

You can also use the `cosmosClient` client object to get a collection or list of TodoItems using a SQL query. Finally, you define the delete method to delete a TodoItem from your list. The following code shows the contents of the `DocDbDao` class:

```
package com.microsoft.azure.documentdb.sample.dao;

import java.util.ArrayList;
import java.util.List;

import com.google.gson.Gson;
import com.azure.cosmos.ConnectionPolicy;
import com.azure.cosmos.ConsistencyLevel;
import com.azure.cosmos.CosmosClient;
import com.azure.cosmos.CosmosClientBuilder;
import com.azure.cosmos.CosmosClientException;
import com.azure.cosmos.CosmosContainer;
import com.azure.cosmos.CosmosDatabase;
import com.azure.cosmos.implementation.Utils;
import com.azure.cosmos.models.CosmosContainerProperties;
import com.azure.cosmos.models.CosmosItemRequestOptions;
import com.azure.cosmos.models.FeedOptions;
import com.azure.cosmos.models.FeedResponse;
import com.azure.cosmos.models.PartitionKey;
import com.fasterxml.jackson.core.JsonProcessingException;
import com.fasterxml.jackson.databind.JsonNode;
import com.fasterxml.jackson.databind.ObjectMapper;
import com.fasterxml.jackson.databind.node.ObjectNode;
import com.microsoft.azure.documentdb.sample.model.TodoItem;

public class DocDbDao implements TodoDao {
    // The name of our database.
    private static final String DATABASE_ID = "TestDB";

    // The name of our collection.
    private static final String CONTAINER_ID = "TestCollection";

    // We'll use Gson for POJO <=> JSON serialization for this example.
    private static Gson gson = new Gson();

    // The Cosmos DB Client
    private static CosmosClient cosmosClient = CosmosClientFactory
            .getCosmosClient();

    // The Cosmos DB database
    private static CosmosDatabase cosmosDatabase = null;

    // The Cosmos DB container
    private static CosmosContainer cosmosContainer = null;

    // For POJO/JsonNode interconversion
    private static final ObjectMapper OBJECT_MAPPER = Utils.getSimpleObjectMapper();

    @Override
    public TodoItem createTodoItem(TodoItem todoItem) {
        // Serialize the TodoItem as a JSON Document.

        JsonNode todoItemJson = OBJECT_MAPPER.valueToTree(todoItem);

        ((ObjectNode)todoItemJson).put("entityType", "todoItem");

        try {
            // Persist the document using the DocumentClient.
            todoItemJson =
                    getContainerCreateResourcesIfNotExist()
                    .createItem(todoItemJson)
                    .getResource();
        } catch (CosmosClientException e) {
```

```
            System.out.println("Error creating TODO item.\n");
            e.printStackTrace();
            return null;
        }

        try {

            return OBJECT_MAPPER.treeToValue(todoItemJson, TodoItem.class);
            //return todoItem;
        } catch (Exception e) {
            System.out.println("Error deserializing created TODO item.\n");
            e.printStackTrace();

            return null;
        }

    }

    @Override
    public TodoItem readTodoItem(String id) {
        // Retrieve the document by id using our helper method.
        JsonNode todoItemJson = getDocumentById(id);

        if (todoItemJson != null) {
            // De-serialize the document in to a TodoItem.
            try {
            return OBJECT_MAPPER.treeToValue(todoItemJson, TodoItem.class);
            } catch (JsonProcessingException e) {
                System.out.println("Error deserializing read TODO item.\n");
                e.printStackTrace();

                return null;
            }
        } else {
            return null;
        }
    }

    @Override
    public List<TodoItem> readTodoItems() {

        List<TodoItem> todoItems = new ArrayList<TodoItem>();

        String sql = "SELECT * FROM root r WHERE r.entityType = 'todoItem'";
        int maxItemCount = 1000;
        int maxDegreeOfParallelism = 1000;
        int maxBufferedItemCount = 100;

        FeedOptions options = new FeedOptions();
        options.setMaxItemCount(maxItemCount);
        options.setMaxBufferedItemCount(maxBufferedItemCount);
        options.setMaxDegreeOfParallelism(maxDegreeOfParallelism);
        options.setRequestContinuation(null);
        options.setPopulateQueryMetrics(false);

        int error_count = 0;
        int error_limit = 10;

        do {

            for (FeedResponse<JsonNode> pageResponse:
                getContainerCreateResourcesIfNotExist()
                    .queryItems(sql, options, JsonNode.class)
                    .iterableByPage()) {

                options.setRequestContinuation(pageResponse.getContinuationToken());

                for (JsonNode item : pageResponse.getElements()) {
```

```
                    try {
                        todoItems.add(OBJECT_MAPPER.treeToValue(item, TodoItem.class));
                    } catch (JsonProcessingException e) {
                        if (error_count < error_limit) {
                            error_count++;
                            if (error_count >= error_limit) {
                                System.out.println("\n...reached max error count.\n");
                            } else {
                                System.out.println("Error deserializing TODO item JsonNode. " +
                                        "This item will not be returned.");
                                e.printStackTrace();
                            }
                        }
                    }

                }
            }

        } while(options.getRequestContinuation() != null);

        return todoItems;
    }

    @Override
    public TodoItem updateTodoItem(String id, boolean isComplete) {
        // Retrieve the document from the database
        JsonNode todoItemJson = getDocumentById(id);

        // You can update the document as a JSON document directly.
        // For more complex operations - you could de-serialize the document in
        // to a POJO, update the POJO, and then re-serialize the POJO back in to
        // a document.
        ((ObjectNode)todoItemJson).put("complete", isComplete);

        try {
            // Persist/replace the updated document.

                    databaseDefinition.setId(DATABASE_ID);

                    databaseCache = cosmosClient.createDatabase(
                            databaseDefinition, null).getResource();
                } catch (CosmosClientException e) {
                    // TODO: Something has gone terribly wrong - the app wasn't
                    // able to query or create the collection.
                    // Verify your connection, endpoint, and key.
                    e.printStackTrace();
                }
            }
        }

        return databaseCache;
    }

    */

    private CosmosContainer getContainerCreateResourcesIfNotExist() {

        try {

            if (cosmosDatabase == null) {
                cosmosDatabase = cosmosClient.createDatabaseIfNotExists(DATABASE_ID).getDatabase();
            }

        } catch(CosmosClientException e) {
            // TODO: Something has gone terribly wrong - the app wasn't
            // able to query or create the collection.
            // Verify your connection, endpoint, and key.
            System.out.println("Something has gone terribly wrong - " +
                               "the app wasn't able to create the Database.\n");
            e.printStackTrace();
        }

        try {

            if (cosmosContainer == null) {
                CosmosContainerProperties properties = new
CosmosContainerProperties(CONTAINER_ID,"/id");
                cosmosContainer = cosmosDatabase.createContainerIfNotExists(properties).getContainer();
```

```
            cosmosContainer = cosmosDatabase.createContainerIfNotExists(properties).getContainer();
        }

    } catch(CosmosClientException e) {
        // TODO: Something has gone terribly wrong - the app wasn't
        // able to query or create the collection.
        // Verify your connection, endpoint, and key.
        System.out.println("Something has gone terribly wrong - " +
                "the app wasn't able to create the Container.\n");
        e.printStackTrace();
    }

    return cosmosContainer;
}

private JsonNode getDocumentById(String id) {

    String sql = "SELECT * FROM root r WHERE r.id='" + id + "'";
    int maxItemCount = 1000;
    int maxDegreeOfParallelism = 1000;
    int maxBufferedItemCount = 100;

    FeedOptions options = new FeedOptions();
    options.setMaxItemCount(maxItemCount);
    options.setMaxBufferedItemCount(maxBufferedItemCount);
    options.setMaxDegreeOfParallelism(maxDegreeOfParallelism);
    options.setRequestContinuation(null);
    options.setPopulateQueryMetrics(false);

    List<JsonNode> itemList = new ArrayList();

    do {

        for (FeedResponse<JsonNode> pageResponse:
            getContainerCreateResourcesIfNotExist()
                .queryItems(sql, options, JsonNode.class)
                .iterableByPage()) {

            options.setRequestContinuation(pageResponse.getContinuationToken());

            for (JsonNode item : pageResponse.getElements()) {
                itemList.add(item);
            }
        }

    } while(options.getRequestContinuation() != null);

    if (itemList.size() > 0) {
        return itemList.get(0);
    } else {
        return null;
    }
}

}
```

5. Next, create a new *TodoDaoFactory.java* file and add the `TodoDaoFactory` class that creates a new DocDbDao object:

```
package com.microsoft.azure.documentdb.sample.dao;

public class TodoDaoFactory {
    private static TodoDao myTodoDao = new DocDbDao();

    public static TodoDao getDao() {
        return myTodoDao;
    }
}
```

Add a controller

Add the *TodoItemController* controller to your application. In this project, you are using Project Lombok to generate the constructor, getters, setters, and a builder. Alternatively, you can write this code manually or have the IDE generate it.:

```
package com.microsoft.azure.documentdb.sample.controller;

import java.util.List;
import java.util.UUID;

import lombok.NonNull;

import com.microsoft.azure.documentdb.sample.dao.TodoDao;
import com.microsoft.azure.documentdb.sample.dao.TodoDaoFactory;
import com.microsoft.azure.documentdb.sample.model.TodoItem;

public class TodoItemController {
    public static TodoItemController getInstance() {
        if (todoItemController == null) {
            todoItemController = new TodoItemController(TodoDaoFactory.getDao());
        }
        return todoItemController;
    }

    private static TodoItemController todoItemController;

    private final TodoDao todoDao;

    TodoItemController(TodoDao todoDao) {
        this.todoDao = todoDao;
    }

    public TodoItem createTodoItem(@NonNull String name,
            @NonNull String category, boolean isComplete) {
        TodoItem todoItem = new TodoItem();

        todoItem.setName(name);
        todoItem.setCategory(category);
        todoItem.setComplete(isComplete);
        todoItem.setId(UUID.randomUUID().toString());

        return todoDao.createTodoItem(todoItem);
    }

    public boolean deleteTodoItem(@NonNull String id) {
        return todoDao.deleteTodoItem(id);
    }

    public TodoItem getTodoItemById(@NonNull String id) {
        return todoDao.readTodoItem(id);
    }

    public List<TodoItem> getTodoItems() {
        return todoDao.readTodoItems();
    }

    public TodoItem updateTodoItem(@NonNull String id, boolean isComplete) {
        return todoDao.updateTodoItem(id, isComplete);
    }
}
```

Create a servlet

Next, create a servlet to route HTTP requests to the controller. Create the *ApiServlet.java* file and define the following code under it:

```
package com.microsoft.azure.documentdb.sample;

import java.io.IOException;

import javax.servlet.ServletException;
```

```
import javax.servlet.annotation.WebServlet;
import javax.servlet.http.HttpServlet;
import javax.servlet.http.HttpServletRequest;
import javax.servlet.http.HttpServletResponse;

import org.apache.commons.lang3.StringUtils;

import com.google.gson.Gson;
import com.microsoft.azure.documentdb.sample.controller.TodoItemController;

/**
 * API Frontend Servlet
 */
@WebServlet("/api")
public class ApiServlet extends HttpServlet {
    // API Keys
    public static final String API_METHOD = "method";

    // API Methods
    public static final String CREATE_TODO_ITEM = "createTodoItem";
    public static final String GET_TODO_ITEMS = "getTodoItems";
    public static final String UPDATE_TODO_ITEM = "updateTodoItem";

    // API Parameters
    public static final String TODO_ITEM_ID = "todoItemId";
    public static final String TODO_ITEM_NAME = "todoItemName";
    public static final String TODO_ITEM_CATEGORY = "todoItemCategory";
    public static final String TODO_ITEM_COMPLETE = "todoItemComplete";

    public static final String MESSAGE_ERROR_INVALID_METHOD = "{'error': 'Invalid method'}";

    private static final long serialVersionUID = 1L;
    private static final Gson gson = new Gson();

    @Override
    protected void doGet(HttpServletRequest request,
            HttpServletResponse response) throws ServletException, IOException {

        String apiResponse = MESSAGE_ERROR_INVALID_METHOD;

        TodoItemController todoItemController = TodoItemController
                .getInstance();

        String id = request.getParameter(TODO_ITEM_ID);
        String name = request.getParameter(TODO_ITEM_NAME);
        String category = request.getParameter(TODO_ITEM_CATEGORY);
        boolean isComplete = StringUtils.equalsIgnoreCase("true",
                request.getParameter(TODO_ITEM_COMPLETE)) ? true : false;

        switch (request.getParameter(API_METHOD)) {
        case CREATE_TODO_ITEM:
            apiResponse = gson.toJson(todoItemController.createTodoItem(name,
                    category, isComplete));
            break;
        case GET_TODO_ITEMS:
            apiResponse = gson.toJson(todoItemController.getTodoItems());
            break;
        case UPDATE_TODO_ITEM:
            apiResponse = gson.toJson(todoItemController.updateTodoItem(id,
                    isComplete));
            break;
        default:
            break;
        }

        response.setCharacterEncoding("UTF-8");
        response.getWriter().println(apiResponse);
    }
```

```
    @Override
    protected void doPost(HttpServletRequest request,
            HttpServletResponse response) throws ServletException, IOException {
        doGet(request, response);
    }
}
```

Wire the rest of the of Java app together

Now that we've finished the fun bits, all that's left is to build a quick user interface and wire it up to your DAO.

1. You need a web user interface to display to the user. Let's re-write the *index.jsp* we created earlier with the following code:

```
<%@ page language="java" contentType="text/html; charset=UTF-8" pageEncoding="UTF-8"%>
<!DOCTYPE html PUBLIC "-//W3C//DTD HTML 4.01 Transitional//EN" "http://www.w3.org/TR/html4/loose.dtd">
<html>
<head>
  <meta http-equiv="Content-Type" content="text/html; charset=UTF-8">
  <meta http-equiv="X-UA-Compatible" content="IE=edge;" />
  <title>Azure DocumentDB Java Sample</title>

  <!-- Bootstrap -->
  <link href="//ajax.aspnetcdn.com/ajax/bootstrap/3.2.0/css/bootstrap.min.css" rel="stylesheet">

  <style>
    /* Add padding to body for fixed nav bar */
    body {
      padding-top: 50px;
    }
  </style>
</head>
<body>
  <!-- Nav Bar -->
  <div class="navbar navbar-inverse navbar-fixed-top" role="navigation">
    <div class="container">
      <div class="navbar-header">
        <a class="navbar-brand" href="#">My Tasks</a>
      </div>
    </div>
  </div>

  <!-- Body -->
  <div class="container">
    <h1>My ToDo List</h1>

    <hr/>

    <!-- The ToDo List -->
    <div class = "todoList">
      <table class="table table-bordered table-striped" id="todoItems">
        <thead>
          <tr>
            <th>Name</th>
            <th>Category</th>
            <th>Complete</th>
          </tr>
        </thead>
        <tbody>
        </tbody>
      </table>

      <!-- Update Button -->
      <div class="todoUpdatePanel">
        <form class="form-horizontal" role="form">
          <button type="button" class="btn btn-primary">Update Tasks</button>
```

```
          <button type="button" class="btn btn-primary">Update Tasks</button>
        </form>
      </div>

    </div>

    <hr/>

    <!-- Item Input Form -->
    <div class="todoForm">
      <form class="form-horizontal" role="form">
        <div class="form-group">
          <label for="inputItemName" class="col-sm-2">Task Name</label>
          <div class="col-sm-10">
            <input type="text" class="form-control" id="inputItemName" placeholder="Enter name">
          </div>
        </div>

        <div class="form-group">
          <label for="inputItemCategory" class="col-sm-2">Task Category</label>
          <div class="col-sm-10">
            <input type="text" class="form-control" id="inputItemCategory" placeholder="Enter
category">
          </div>
        </div>

        <button type="button" class="btn btn-primary">Add Task</button>
      </form>
    </div>

  </div>

  <!-- Placed at the end of the document so the pages load faster -->
  <script src="//ajax.aspnetcdn.com/ajax/jQuery/jquery-2.1.1.min.js"></script>
  <script src="//ajax.aspnetcdn.com/ajax/bootstrap/3.2.0/bootstrap.min.js"></script>
  <script src="assets/todo.js"></script>
</body>
</html>
```

2. Finally, write some client-side JavaScript to tie the web user interface and the servlet together:

```
/**
 * ToDo App
 */

var todoApp = {
  /*
   * API methods to call Java backend.
   */
  apiEndpoint: "api",

  createTodoItem: function(name, category, isComplete) {
    $.post(todoApp.apiEndpoint, {
        "method": "createTodoItem",
        "todoItemName": name,
        "todoItemCategory": category,
        "todoItemComplete": isComplete
      },
      function(data) {
        var todoItem = data;
        todoApp.addTodoItemToTable(todoItem.id, todoItem.name, todoItem.category, todoItem.complete);
      },
      "json");
  },

  getTodoItems: function() {
    $.post(todoApp.apiEndpoint, {
        "method": "getTodoItems"
```

```
        "method": "getTodoItems"
      },
      function(data) {
        var todoItemArr = data;
        $.each(todoItemArr, function(index, value) {
          todoApp.addTodoItemToTable(value.id, value.name, value.category, value.complete);
        });
      },
      "json");
  },

  updateTodoItem: function(id, isComplete) {
    $.post(todoApp.apiEndpoint, {
        "method": "updateTodoItem",
        "todoItemId": id,
        "todoItemComplete": isComplete
      },
      function(data) {},
      "json");
  },

  /*
   * UI Methods
   */
  addTodoItemToTable: function(id, name, category, isComplete) {
    var rowColor = isComplete ? "active" : "warning";

    todoApp.ui_table().append($("<tr>")
      .append($("<td>").text(name))
      .append($("<td>").text(category))
      .append($("<td>")
        .append($("<input>")
          .attr("type", "checkbox")
          .attr("id", id)
          .attr("checked", isComplete)
          .attr("class", "isComplete")
        ))
      .addClass(rowColor)
    );
  },

  /*
   * UI Bindings
   */
  bindCreateButton: function() {
    todoApp.ui_createButton().click(function() {
      todoApp.createTodoItem(todoApp.ui_createNameInput().val(),
todoApp.ui_createCategoryInput().val(), false);
      todoApp.ui_createNameInput().val("");
      todoApp.ui_createCategoryInput().val("");
    });
  },

  bindUpdateButton: function() {
    todoApp.ui_updateButton().click(function() {
      // Disable button temporarily.
      var myButton = $(this);
      var originalText = myButton.text();
      $(this).text("Updating...");
      $(this).prop("disabled", true);

      // Call api to update todo items.
      $.each(todoApp.ui_updateId(), function(index, value) {
        todoApp.updateTodoItem(value.name, value.value);
        $(value).remove();
      });

      // Re-enable button.
      setTimeout(function() {
        myButton.prop("disabled", false);
```

```
      myButton.prop("disabled", false);
      myButton.text(originalText);
    }, 500);
  });
},

bindUpdateCheckboxes: function() {
  todoApp.ui_table().on("click", ".isComplete", function(event) {
    var checkboxElement = $(event.currentTarget);
    var rowElement = $(event.currentTarget).parents('tr');
    var id = checkboxElement.attr('id');
    var isComplete = checkboxElement.is(':checked');

    // Togle table row color
    if (isComplete) {
      rowElement.addClass("active");
      rowElement.removeClass("warning");
    } else {
      rowElement.removeClass("active");
      rowElement.addClass("warning");
    }

    // Update hidden inputs for update panel.
    todoApp.ui_updateForm().children("input[name='" + id + "']").remove();

    todoApp.ui_updateForm().append($("<input>")
      .attr("type", "hidden")
      .attr("class", "updateComplete")
      .attr("name", id)
      .attr("value", isComplete));

  });
},

/*
 * UI Elements
 */
ui_createNameInput: function() {
  return $(".todoForm #inputItemName");
},

ui_createCategoryInput: function() {
  return $(".todoForm #inputItemCategory");
},

ui_createButton: function() {
  return $(".todoForm button");
},

ui_table: function() {
  return $(".todoList table tbody");
},

ui_updateButton: function() {
  return $(".todoUpdatePanel button");
},

ui_updateForm: function() {
  return $(".todoUpdatePanel form");
},

ui_updateId: function() {
  return $(".todoUpdatePanel .updateComplete");
},

/*
 * Install the TodoApp
 */
install: function() {
```

```
    todoApp.bindCreateButton();
    todoApp.bindUpdateButton();
    todoApp.bindUpdateCheckboxes();

    todoApp.getTodoItems();
  }
};

$(document).ready(function() {
  todoApp.install();
});
```

3. Now all that's left is to test the application. Run the application locally, and add some Todo items by filling in the item name and category and clicking **Add Task**. After the item appears, you can update whether it's complete by toggling the checkbox and clicking **Update Tasks**.

Deploy your Java application to Azure Web Sites

Azure Web Sites makes deploying Java applications as simple as exporting your application as a WAR file and either uploading it via source control (e.g. Git) or FTP.

1. To export your application as a WAR file, right-click on your project in **Project Explorer**, click **Export**, and then click **WAR File**.

2. In the **WAR Export** window, do the following:

   - In the Web project box, enter azure-documentdb-java-sample.
   - In the Destination box, choose a destination to save the WAR file.
   - Click **Finish**.
3. Now that you have a WAR file in hand, you can simply upload it to your Azure Web Site's **webapps** directory. For instructions on uploading the file, see Add a Java application to Azure App Service Web Apps. After the WAR file is uploaded to the webapps directory, the runtime environment will detect that you've added it and will automatically load it.

4. To view your finished product, navigate to `http://YOUR\_SITE\_NAME.azurewebsites.net/azure-java-sample/` and start adding your tasks!

Get the project from GitHub

All the samples in this tutorial are included in the todo project on GitHub. To import the todo project into Eclipse, ensure you have the software and resources listed in the Prerequisites section, then do the following:

1. Install Project Lombok. Lombok is used to generate constructors, getters, setters in the project. Once you have downloaded the lombok.jar file, double-click it to install it or install it from the command line.

2. If Eclipse is open, close it and restart it to load Lombok.

3. In Eclipse, on the **File** menu, click **Import**.

4. In the **Import** window, click **Git**, click **Projects from Git**, and then click **Next**.

5. On the **Select Repository Source** screen, click **Clone URI**.

6. On the **Source Git Repository** screen, in the **URI** box, enter https://github.com/Azure-Samples/documentdb-java-todo-app.git, and then click **Next**.

7. On the **Branch Selection** screen, ensure that **main** is selected, and then click **Next**.

8. On the **Local Destination** screen, click **Browse** to select a folder where the repository can be copied, and then click **Next**.

9. On the **Select a wizard to use for importing projects** screen, ensure that **Import existing projects** is selected, and then click **Next**.
10. On the **Import Projects** screen, unselect the **DocumentDB** project, and then click **Finish**. The DocumentDB project contains the Azure Cosmos DB Java SDK, which we will add as a dependency instead.
11. In **Project Explorer**, navigate to azure-documentdb-java-sample\src\com.microsoft.azure.documentdb.sample.dao\DocumentClientFactory.java and replace the HOST and MASTER_KEY values with the URI and PRIMARY KEY for your Azure Cosmos DB account, and then save the file. For more information, see Step 1. Create an Azure Cosmos database account.
12. In **Project Explorer**, right-click the **azure-documentdb-java-sample**, click **Build Path**, and then click **Configure Build Path**.
13. On the **Java Build Path** screen, in the right pane, select the **Libraries** tab, and then click **Add External JARs**. Navigate to the location of the lombok.jar file, and click **Open**, and then click **OK**.
14. Use step 12 to open the **Properties** window again, and then in the left pane click **Targeted Runtimes**.
15. On the **Targeted Runtimes** screen, click **New**, select **Apache Tomcat v7.0**, and then click **OK**.
16. Use step 12 to open the **Properties** window again, and then in the left pane click **Project Facets**.
17. On the **Project Facets** screen, select **Dynamic Web Module** and **Java**, and then click **OK**.
18. On the **Servers** tab at the bottom of the screen, right-click **Tomcat v7.0 Server at localhost** and then click **Add and Remove**.
19. On the **Add and Remove** window, move **azure-documentdb-java-sample** to the **Configured** box, and then click **Finish**.
20. In the **Servers** tab, right-click **Tomcat v7.0 Server at localhost**, and then click **Restart**.
21. In a browser, navigate to `http://localhost:8080/azure-documentdb-java-sample/` and start adding to your task list. Note that if you changed your default port values, change 8080 to the value you selected.
22. To deploy your project to an Azure web site, see Step 6. Deploy your application to Azure Web Sites.

Next steps

Build a node.js application with Azure Cosmos DB

Tutorial: Build a Node.js web app using the JavaScript SDK to manage a SQL API account in Azure Cosmos DB

11/2/2020 • 13 minutes to read • Edit Online

APPLIES TO: SQL API

As a developer, you might have applications that use NoSQL document data. You can use a SQL API account in Azure Cosmos DB to store and access this document data. This Node.js tutorial shows you how to store and access data from a SQL API account in Azure Cosmos DB by using a Node.js Express application that is hosted on the Web Apps feature of Microsoft Azure App Service. In this tutorial, you will build a web-based application (Todo app) that allows you to create, retrieve, and complete tasks. The tasks are stored as JSON documents in Azure Cosmos DB.

This tutorial demonstrates how to create a SQL API account in Azure Cosmos DB by using the Azure portal. You then build and run a web app that is built on the Node.js SDK to create a database and container, and add items to the container. This tutorial uses JavaScript SDK version 3.0.

This tutorial covers the following tasks:

- Create an Azure Cosmos DB account
- Create a new Node.js application
- Connect the application to Azure Cosmos DB
- Run and deploy the application to Azure

Prerequisites

Before following the instructions in this article, ensure that you have the following resources:

- If you don't have an Azure subscription, create a free account before you begin.

  You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

- Node.js version 6.10 or higher.
- Express generator (you can install Express via `npm install express-generator -g`)
- Install Git on your local workstation.

Create an Azure Cosmos DB account

Let's start by creating an Azure Cosmos DB account. If you already have an account or if you are using the Azure Cosmos DB Emulator for this tutorial, you can skip to Step 2: Create a new Node.js application.

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.

4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.

SETTING	VALUE	DESCRIPTION
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Go to the Azure Cosmos DB account page, and select **Keys**. Copy the values to use in the web application you create next.

Create a new Node.js application

Now let's learn to create a basic Hello World Node.js project using the Express framework.

1. Open your favorite terminal, such as the Node.js command prompt.

2. Navigate to the directory in which you'd like to store the new application.

3. Use the express generator to generate a new application called **todo**.

```
express todo
```

4. Open the **todo** directory and install dependencies.

```
cd todo
npm install
```

5. Run the new application.

```
npm start
```

6. You can view your new application by navigating your browser to `http://localhost:3000`.

Stop the application by using CTRL+C in the terminal window, and select **y** to terminate the batch job.

Install the required modules

The **package.json** file is one of the files created in the root of the project. This file contains a list of additional modules that are required for your Node.js application. When you deploy this application to Azure, this file is used to determine which modules should be installed on Azure to support your application. Install two more packages for this tutorial.

1. Install the **@azure/cosmos** module via npm.

```
npm install @azure/cosmos
```

Connect the Node.js application to Azure Cosmos DB

Now that you have completed the initial setup and configuration, next you will write code that is required by the todo application to communicate with Azure Cosmos DB.

Create the model

1. At the root of your project directory, create a new directory named **models**.

2. In the **models** directory, create a new file named **taskDao.js**. This file contains code required to create the database and container. It also defines methods to read, update, create, and find tasks in Azure Cosmos DB.

3. Copy the following code into the **taskDao.js** file:

```
// @ts-check
const CosmosClient = require('@azure/cosmos').CosmosClient
const debug = require('debug')('todo:taskDao')

// For simplicity we'll set a constant partition key
const partitionKey = undefined
class TaskDao {
  /**
```

```
     * Manages reading, adding, and updating Tasks in Cosmos DB
     * @param {CosmosClient} cosmosClient
     * @param {string} databaseId
     * @param {string} containerId
     */
    constructor(cosmosClient, databaseId, containerId) {
      this.client = cosmosClient
      this.databaseId = databaseId
      this.collectionId = containerId

      this.database = null
      this.container = null
    }

    async init() {
      debug('Setting up the database...')
      const dbResponse = await this.client.databases.createIfNotExists({
        id: this.databaseId
      })
      this.database = dbResponse.database
      debug('Setting up the database...done!')
      debug('Setting up the container...')
      const coResponse = await this.database.containers.createIfNotExists({
        id: this.collectionId
      })
      this.container = coResponse.container
      debug('Setting up the container...done!')
    }

    async find(querySpec) {
      debug('Querying for items from the database')
      if (!this.container) {
        throw new Error('Collection is not initialized.')
      }
      const { resources } = await this.container.items.query(querySpec).fetchAll()
      return resources
    }

    async addItem(item) {
      debug('Adding an item to the database')
      item.date = Date.now()
      item.completed = false
      const { resource: doc } = await this.container.items.create(item)
      return doc
    }

    async updateItem(itemId) {
      debug('Update an item in the database')
      const doc = await this.getItem(itemId)
      doc.completed = true

      const { resource: replaced } = await this.container
        .item(itemId, partitionKey)
        .replace(doc)
      return replaced
    }

    async getItem(itemId) {
      debug('Getting an item from the database')
      const { resource } = await this.container.item(itemId, partitionKey).read()
      return resource
    }
  }

  module.exports = TaskDao
```

4. Save and close the **taskDao.js** file.

Create the controller

1. In the **routes** directory of your project, create a new file named **tasklist.js**.

2. Add the following code to **tasklist.js**. This code loads the CosmosClient and async modules, which are used by **tasklist.js**. This code also defines the **TaskList** class, which is passed as an instance of the **TaskDao** object we defined earlier:

```
const TaskDao = require("../models/TaskDao");

class TaskList {
  /**
   * Handles the various APIs for displaying and managing tasks
   * @param {TaskDao} taskDao
   */
  constructor(taskDao) {
    this.taskDao = taskDao;
  }
  async showTasks(req, res) {
    const querySpec = {
      query: "SELECT * FROM root r WHERE r.completed=@completed",
      parameters: [
        {
          name: "@completed",
          value: false
        }
      ]
    };

    const items = await this.taskDao.find(querySpec);
    res.render("index", {
      title: "My ToDo List ",
      tasks: items
    });
  }

  async addTask(req, res) {
    const item = req.body;

    await this.taskDao.addItem(item);
    res.redirect("/");
  }

  async completeTask(req, res) {
    const completedTasks = Object.keys(req.body);
    const tasks = [];

    completedTasks.forEach(task => {
      tasks.push(this.taskDao.updateItem(task));
    });

    await Promise.all(tasks);

    res.redirect("/");
  }
}

module.exports = TaskList;
```

3. Save and close the **tasklist.js** file.

Add config.js

1. At the root of your project directory, create a new file named **config.js**.

2. Add the following code to **config.js** file. This code defines configuration settings and values needed for our

application.

```
const config = {};

config.host = process.env.HOST || "[the endpoint URI of your Azure Cosmos DB account]";
config.authKey =
  process.env.AUTH_KEY || "[the PRIMARY KEY value of your Azure Cosmos DB account";
config.databaseId = "ToDoList";
config.containerId = "Items";

if (config.host.includes("https://localhost:")) {
  console.log("Local environment detected");
  console.log("WARNING: Disabled checking of self-signed certs. Do not have this code in production.");
  process.env.NODE_TLS_REJECT_UNAUTHORIZED = "0";
  console.log(`Go to http://localhost:${process.env.PORT || '3000'} to try the sample.`);
}

module.exports = config;
```

3. In the **config.js** file, update the values of HOST and AUTH_KEY using the values found in the Keys page of your Azure Cosmos DB account on the Azure portal.

4. Save and close the **config.js** file.

Modify app.js

1. In the project directory, open the **app.js** file. This file was created earlier when the Express web application was created.

2. Add the following code to the **app.js** file. This code defines the config file to be used, and loads the values into some variables that you will use in the next sections.

```
const CosmosClient = require('@azure/cosmos').CosmosClient
const config = require('./config')
const TaskList = require('./routes/tasklist')
const TaskDao = require('./models/taskDao')

const express = require('express')
const path = require('path')
const logger = require('morgan')
const cookieParser = require('cookie-parser')
const bodyParser = require('body-parser')

const app = express()

// view engine setup
app.set('views', path.join(__dirname, 'views'))
app.set('view engine', 'jade')

// uncomment after placing your favicon in /public
//app.use(favicon(path.join(__dirname, 'public', 'favicon.ico')));
app.use(logger('dev'))
app.use(bodyParser.json())
app.use(bodyParser.urlencoded({ extended: false }))
app.use(cookieParser())
app.use(express.static(path.join(__dirname, 'public')))

//Todo App:
const cosmosClient = new CosmosClient({
  endpoint: config.host,
  key: config.authKey
})
const taskDao = new TaskDao(cosmosClient, config.databaseId, config.containerId)
const taskList = new TaskList(taskDao)
taskDao
```

```
  .init(err => {
    console.error(err)
  })
  .catch(err => {
    console.error(err)
    console.error(
      'Shutting down because there was an error settinig up the database.'
    )
    process.exit(1)
  })

app.get('/', (req, res, next) => taskList.showTasks(req, res).catch(next))
app.post('/addtask', (req, res, next) => taskList.addTask(req, res).catch(next))
app.post('/completetask', (req, res, next) =>
  taskList.completeTask(req, res).catch(next)
)
app.set('view engine', 'jade')

// catch 404 and forward to error handler
app.use(function(req, res, next) {
  const err = new Error('Not Found')
  err.status = 404
  next(err)
})

// error handler
app.use(function(err, req, res, next) {
  // set locals, only providing error in development
  res.locals.message = err.message
  res.locals.error = req.app.get('env') === 'development' ? err : {}

  // render the error page
  res.status(err.status || 500)
  res.render('error')
})

module.exports = app
```

3. Finally, save and close the **app.js** file.

Build a user interface

Now let's build the user interface so that a user can interact with the application. The Express application we created in the previous sections uses **Jade** as the view engine.

1. The **layout.jade** file in the **views** directory is used as a global template for other **.jade** files. In this step you will modify it to use Twitter Bootstrap, which is a toolkit used to design a website.

2. Open the **layout.jade** file found in the **views** folder and replace the contents with the following code:

```
doctype html
html
  head
    title= title
    link(rel='stylesheet', href='//ajax.aspnetcdn.com/ajax/bootstrap/3.3.2/css/bootstrap.min.css')
    link(rel='stylesheet', href='/stylesheets/style.css')
  body
    nav.navbar.navbar-inverse.navbar-fixed-top
      div.navbar-header
        a.navbar-brand(href='#') My Tasks
    block content
    script(src='//ajax.aspnetcdn.com/ajax/jQuery/jquery-1.11.2.min.js')
    script(src='//ajax.aspnetcdn.com/ajax/bootstrap/3.3.2/bootstrap.min.js')
```

This code tells the **Jade** engine to render some HTML for our application, and creates a **block** called **content** where we can supply the layout for our content pages. Save and close the **layout.jade** file.

3. Now open the **index.jade** file, the view that will be used by our application, and replace the content of the file with the following code:

```
extends layout
block content
     h1 #{title}
     br

     form(action="/completetask", method="post")
      table.table.table-striped.table-bordered
         tr
           td Name
           td Category
           td Date
           td Complete
         if (typeof tasks === "undefined")
           tr
             td
         else
           each task in tasks
             tr
               td #{task.name}
               td #{task.category}
               - var date  = new Date(task.date);
               - var day   = date.getDate();
               - var month = date.getMonth() + 1;
               - var year  = date.getFullYear();
               td #{month + "/" + day + "/" + year}
               td
                if(task.completed)
                 input(type="checkbox", name="#{task.id}", value="#{!task.completed}",
checked=task.completed)
                else
                 input(type="checkbox", name="#{task.id}", value="#{!task.completed}",
checked=task.completed)
       button.btn.btn-primary(type="submit") Update tasks
     hr
     form.well(action="/addtask", method="post")
       label Item Name:
       input(name="name", type="textbox")
       label Item Category:
       input(name="category", type="textbox")
       br
       button.btn(type="submit") Add item
```

This code extends layout, and provides content for the **content** placeholder we saw in the **layout.jade** file earlier. In this layout, we created two HTML forms.

The first form contains a table for your data and a button that allows you to update items by posting to **/completeTask** method of the controller.

The second form contains two input fields and a button that allows you to create a new item by posting to **/addtask** method of the controller. That's all we need for the application to work.

Run your application locally

Now that you have built the application, you can run it locally by using the following steps:

1. To test the application on your local machine, run `npm start` in the terminal to start your application, and then refresh the `http://localhost:3000` browser page. The page should now look as shown in the following

screenshot:

> **TIP**
> If you receive an error about the indent in the layout.jade file or the index.jade file, ensure that the first two lines in both files are left-justified, with no spaces. If there are spaces before the first two lines, remove them, save both files, and then refresh your browser window.

2. Use the Item, Item Name, and Category fields to enter a new task, and then select **Add Item**. It creates a document in Azure Cosmos DB with those properties.

3. The page should update to display the newly created item in the ToDo list.

4. To complete a task, select the check box in the Complete column, and then select **Update tasks**. It updates the document you already created and removes it from the view.

5. To stop the application, press CTRL+C in the terminal window and then select **Y** to terminate the batch job.

Deploy your application to Web Apps

After your application succeeds locally, you can deploy it to Azure by using the following steps:

1. If you haven't already done so, enable a git repository for your Web Apps application.

2. Add your Web Apps application as a git remote.

```
git remote add azure https://username@your-azure-website.scm.azurewebsites.net:443/your-azure-website.git
```

3. Deploy the application by pushing it to the remote.

```
git push azure master
```

4. In a few seconds, your web application is published and launched in a browser.

Clean up resources

When these resources are no longer needed, you can delete the resource group, Azure Cosmos DB account, and all the related resources. To do so, select the resource group that you used for the Azure Cosmos DB account, select **Delete**, and then confirm the name of the resource group to delete.

Next steps

Tutorial: Build mobile applications with Xamarin and Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

Most mobile apps need to store data in the cloud, and Azure Cosmos DB is a cloud database for mobile apps. It has everything a mobile developer need. It is a fully managed database as a service that scales on demand. It can bring your data to your application transparently, wherever your users are located around the globe. By using the Azure Cosmos DB .NET Core SDK, you can enable Xamarin mobile apps to interact directly with Azure Cosmos DB, without a middle tier.

This article provides a tutorial for building mobile apps with Xamarin and Azure Cosmos DB. You can find the complete source code for the tutorial at Xamarin and Azure Cosmos DB on GitHub, including how to manage users and permissions.

Azure Cosmos DB capabilities for mobile apps

Azure Cosmos DB provides the following key capabilities for mobile app developers:

- Rich queries over schemaless data. Azure Cosmos DB stores data as schemaless JSON documents in heterogeneous collections. It offers rich and fast queries without the need to worry about schemas or indexes.
- Fast throughput. It takes only a few milliseconds to read and write documents with Azure Cosmos DB. Developers can specify the throughput they need, and Azure Cosmos DB honors it with 99.99% availability SLA for all single region accounts and all multi-region accounts with relaxed consistency, and 99.999% read availability on all multi-region database accounts.
- Limitless scale. Your Azure Cosmos containers grow as your app grows. You can start with small data size and throughput of hundreds of requests per second. Your collections or databases can grow to petabytes of data and arbitrarily large throughput with hundreds of millions of requests per second.
- Globally distributed. Mobile app users are on the go, often across the world. Azure Cosmos DB is a globally distributed database. Click the map to make your data accessible to your users.
- Built-in rich authorization. With Azure Cosmos DB, you can easily implement popular patterns like per-user data or multiuser shared data, without complex custom authorization code.
- Geospatial queries. Many mobile apps offer geo-contextual experiences today. With first-class support for geospatial types, Azure Cosmos DB makes creating these experiences easy to accomplish.
- Binary attachments. Your app data often includes binary blobs. Native support for attachments makes it easier

to use Azure Cosmos DB as a one-stop shop for your app data.

Azure Cosmos DB and Xamarin tutorial

The following tutorial shows how to build a mobile application by using Xamarin and Azure Cosmos DB. You can find the complete source code for the tutorial at Xamarin and Azure Cosmos DB on GitHub.

Get started

It's easy to get started with Azure Cosmos DB. Go to the Azure portal, and create a new Azure Cosmos DB account. Click the **Quick start** tab. Download the Xamarin Forms to-do list sample that is already connected to your Azure Cosmos DB account.

Or if you have an existing Xamarin app, you can add the Azure Cosmos DB NuGet package. Azure Cosmos DB supports Xamarin.iOS, Xamarin.Android, and Xamarin Forms shared libraries.

Work with data

Your data records are stored in Azure Cosmos DB as schemaless JSON documents in heterogeneous collections. You can store documents with different structures in the same collection:

```
var result = await client.CreateDocumentAsync(collectionLink, todoItem);
```

In your Xamarin projects, you can use language-integrated queries over schemaless data:

```
var query = await client.CreateDocumentQuery<ToDoItem>(collectionLink)
                .Where(todoItem => todoItem.Complete == false)
                .AsDocumentQuery();

Items = new List<TodoItem>();
while (query.HasMoreResults) {
    Items.AddRange(await query.ExecuteNextAsync<TodoItem>());
}
```

Add users

Like many get started samples, the Azure Cosmos DB sample you downloaded authenticates to the service by using a primary key hardcoded in the app's code. This default is not a good practice for an app you intend to run anywhere except on your local emulator. If an unauthorized user obtained the primary key, all the data across your Azure Cosmos DB account could be compromised. Instead, you want your app to access only the records for the signed-in user. Azure Cosmos DB allows developers to grant application read or read/write permission to a collection, a set of documents grouped by a partition key, or a specific document.

Follow these steps to modify the to-do list app to a multiuser to-do list app:

1. Add Login to your app by using Facebook, Active Directory, or any other provider.
2. Create an Azure Cosmos DB UserItems collection with **/userId** as the partition key. Specifying the partition key for your collection allows Azure Cosmos DB to scale infinitely as the number of your app users grows, while continuing to offer fast queries.
3. Add Azure Cosmos DB Resource Token Broker. This simple Web API authenticates users and issues short-lived tokens to signed-in users with access only to the documents within their partition. In this example, Resource Token Broker is hosted in App Service.
4. Modify the app to authenticate to Resource Token Broker with Facebook, and request the resource tokens for the signed-in Facebook users. You can then access their data in the UserItems collection.

You can find a complete code sample of this pattern at Resource Token Broker on GitHub. This diagram illustrates the solution:

If you want two users to have, access to the same to-do list, you can add additional permissions to the access

token in Resource Token Broker.

Scale on demand

Azure Cosmos DB is a managed database as a service. As your user base grows, you don't need to worry about provisioning VMs or increasing cores. All you need to tell Azure Cosmos DB is how many operations per second (throughput) your app needs. You can specify the throughput via the **Scale** tab by using a measure of throughput called Request Units (RUs) per second. For example, a read operation on a 1-KB document requires one RU. You can also add alerts to the **Throughput** metric to monitor the traffic growth and programmatically change the throughput as alerts fire.

Go planet scale

As your app gains popularity, you might gain users across the globe. Or maybe you want to be prepared for unforeseen events. Go to the Azure portal, and open your Azure Cosmos DB account. Click the map to make your data continuously replicate to any number of regions across the world. This capability makes your data available wherever your users are. You can also add failover policies to be prepared for contingencies.

Congratulations. You have completed the solution and have a mobile app with Xamarin and Azure Cosmos DB. Follow similar steps to build Cordova apps by using the Azure Cosmos DB JavaScript SDK and native iOS/Android apps by using Azure Cosmos DB REST APIs.

Next steps

- View the source code for Xamarin and Azure Cosmos DB on GitHub.

Tutorial: Use Data migration tool to migrate your data to Azure Cosmos DB

12/4/2020 • 25 minutes to read • Edit Online

APPLIES TO: SQL API

This tutorial provides instructions on using the Azure Cosmos DB Data Migration tool, which can import data from various sources into Azure Cosmos containers and tables. You can import from JSON files, CSV files, SQL, MongoDB, Azure Table storage, Amazon DynamoDB, and even Azure Cosmos DB SQL API collections. You migrate that data to collections and tables for use with Azure Cosmos DB. The Data Migration tool can also be used when migrating from a single partition collection to a multi-partition collection for the SQL API.

> **NOTE**
> The Azure Cosmos DB Data Migration tool is an open source tool designed for small migrations. For larger migrations, view our guide for ingesting data.

- **SQL API** - You can use any of the source options provided in the Data Migration tool to import data at a small scale. Learn about migration options for importing data at a large scale.
- **Table API** - You can use the Data Migration tool or AzCopy to import data. For more information, see Import data for use with the Azure Cosmos DB Table API.
- **Azure Cosmos DB's API for MongoDB** - The Data Migration tool doesn't support Azure Cosmos DB's API for MongoDB either as a source or as a target. If you want to migrate the data in or out of collections in Azure Cosmos DB, refer to How to migrate MongoDB data to a Cosmos database with Azure Cosmos DB's API for MongoDB for instructions. You can still use the Data Migration tool to export data from MongoDB to Azure Cosmos DB SQL API collections for use with the SQL API.
- **Cassandra API** - The Data Migration tool isn't a supported import tool for Cassandra API accounts. Learn about migration options for importing data into Cassandra API
- **Gremlin API** - The Data Migration tool isn't a supported import tool for Gremlin API accounts at this time. Learn about migration options for importing data into Gremlin API

This tutorial covers the following tasks:

- Installing the Data Migration tool
- Importing data from different data sources
- Exporting from Azure Cosmos DB to JSON

Prerequisites

Before following the instructions in this article, ensure that you do the following steps:

- **Install** Microsoft .NET Framework 4.51 or higher.
- **Increase throughput:** The duration of your data migration depends on the amount of throughput you set up for an individual collection or a set of collections. Be sure to increase the throughput for larger data migrations. After you've completed the migration, decrease the throughput to save costs. For more information about increasing throughput in the Azure portal, see performance levels and pricing tiers in Azure Cosmos DB.
- **Create Azure Cosmos DB resources:** Before you start the migrating data, pre-create all your collections from the Azure portal. To migrate to an Azure Cosmos DB account that has database level throughput, provide a partition key when you create the Azure Cosmos containers.

> **IMPORTANT**
> To make sure that the Data migration tool uses Transport Layer Security (TLS) 1.2 when connecting to your Azure Cosmos accounts, use the .NET Framework version 4.7 or follow the instructions found in this article.

Overview

The Data Migration tool is an open-source solution that imports data to Azure Cosmos DB from a variety of sources, including:

- JSON files
- MongoDB
- SQL Server
- CSV files
- Azure Table storage
- Amazon DynamoDB
- HBase
- Azure Cosmos containers

While the import tool includes a graphical user interface (dtui.exe), it can also be driven from the command-line (dt.exe). In fact, there's an option to output the associated command after setting up an import through the UI. You can transform tabular source data, such as SQL Server or CSV files, to create hierarchical relationships (subdocuments) during import. Keep reading to learn more about source options, sample commands to import from each source, target options, and viewing import results.

> **NOTE**
> You should only use the Azure Cosmos DB migration tool for small migrations. For large migrations, view our guide for ingesting data.

Installation

The migration tool source code is available on GitHub in this repository. You can download and compile the solution locally, or download a pre-compiled binary, then run either:

- **Dtui.exe**: Graphical interface version of the tool
- **Dt.exe**: Command-line version of the tool

Select data source

Once you've installed the tool, it's time to import your data. What kind of data do you want to import?

- JSON files
- MongoDB
- MongoDB Export files
- SQL Server
- CSV files
- Azure Table storage
- Amazon DynamoDB
- Blob
- Azure Cosmos containers
- HBase
- Azure Cosmos DB bulk import
- Azure Cosmos DB sequential record import

Import JSON files

The JSON file source importer option allows you to import one or more single document JSON files or JSON files that each have an array of JSON documents. When adding folders that have JSON files to import, you have the option of recursively searching for files in subfolders.

The connection string is in the following format:

```
AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>
```

- The `<CosmosDB Endpoint>` is the endpoint URI. You can get this value from the Azure portal. Navigate to your Azure Cosmos account. Open the **Overview** pane and copy the **URI** value.
- The `<AccountKey>` is the "Password" or **PRIMARY KEY**. You can get this value from the Azure portal. Navigate to your Azure Cosmos account. Open the **Connection Strings** or **Keys** pane, and copy the "Password" or **PRIMARY KEY** value.
- The `<CosmosDB Database>` is the CosmosDB database name.

Example:

```
AccountEndpoint=https://myCosmosDBName.documents.azure.com:443/;AccountKey=wJmFRYna6ttQ79ATmrTMKql8vPri84QBiHTt6oinFkZRvoe7Vv81x9sn6zlVlBY10bEPMgGM982wfYXpWXWB9w==;Database=myDatabaseN
```

> **NOTE**
> Use the Verify command to ensure that the Cosmos DB account specified in the connection string field can be accessed.

Here are some command-line samples to import JSON files:

```
#Import a single JSON file
dt.exe /s:JsonFile /s.Files:.\Sessions.json /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB
Database>;" /t.Collection:Sessions /t.CollectionThroughput:2500

#Import a directory of JSON files
dt.exe /s:JsonFile /s.Files:C:\TESessions\*.json /t:DocumentDBBulk /t.ConnectionString:" AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB
Database>;" /t.Collection:Sessions /t.CollectionThroughput:2500

#Import a directory (including sub-directories) of JSON files
dt.exe /s:JsonFile /s.Files:C:\LastFMMusic\**\*.json /t:DocumentDBBulk /t.ConnectionString:" AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=
<CosmosDB Database>;" /t.Collection:Music /t.CollectionThroughput:2500

#Import a directory (single), directory (recursive), and individual JSON files
dt.exe /s:JsonFile
/s.Files:C:\Tweets\*.*;C:\LargeDocs\**\*.*;C:\TESessions\Session48172.json;C:\TESessions\Session48173.json;C:\TESessions\Session48174.json;C:\TESessions\Session48175.jso
n;C:\TESessions\Session48177.json /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;"
/t.Collection:subs /t.CollectionThroughput:2500

#Import a single JSON file and partition the data across 4 collections
dt.exe /s:JsonFile /s.Files:D:\\CompanyData\\Companies.json /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB
Key>;Database=<CosmosDB Database>;" /t.Collection:comp[1-4] /t.PartitionKey:name /t.CollectionThroughput:2500
```

Import from MongoDB

> **IMPORTANT**
>
> If you're importing to a Cosmos account configured with Azure Cosmos DB's API for MongoDB, follow these instructions.

With the MongoDB source importer option, you can import from a single MongoDB collection, optionally filter documents using a query, and modify the document structure by using a projection.

The connection string is in the standard MongoDB format:

```
mongodb://<dbuser>:<dbpassword>@<host>:<port>/<database>
```

> **NOTE**
>
> Use the Verify command to ensure that the MongoDB instance specified in the connection string field can be accessed.

Enter the name of the collection from which data will be imported. You may optionally specify or provide a file for a query, such as `{pop: {$gt:5000}}`, or a projection, such as `{loc:0}`, to both filter and shape the data that you're importing.

Here are some command-line samples to import from MongoDB:

```
#Import all documents from a MongoDB collection
dt.exe /s:MongoDB /s.ConnectionString:mongodb://<dbuser>:<dbpassword>@<host>:<port>/<database> /s.Collection:zips /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=
<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:BulkZips /t.IdField:_id /t.CollectionThroughput:2500

#Import documents from a MongoDB collection which match the query and exclude the loc field
dt.exe /s:MongoDB /s.ConnectionString:mongodb://<dbuser>:<dbpassword>@<host>:<port>/<database> /s.Collection:zips /s.Query:{pop:{$gt:50000}} /s.Projection:{loc:0}
/t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:BulkZipsTransform
/t.IdField:_id/t.CollectionThroughput:2500
```

Import MongoDB export files

> **IMPORTANT**
>
> If you're importing to an Azure Cosmos DB account with support for MongoDB, follow these instructions.

The MongoDB export JSON file source importer option allows you to import one or more JSON files produced from the mongoexport utility.

When adding folders that have MongoDB export JSON files for import, you have the option of recursively searching for files in subfolders.

Here is a command-line sample to import from MongoDB export JSON files:

```
dt.exe /s:MongoDBExport /s.Files:D:\mongoemployees.json /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=
<CosmosDB Database>;" /t.Collection:employees /t.IdField:_id /t.Dates:Epoch /t.CollectionThroughput:2500
```

Import from SQL Server

The SQL source importer option allows you to import from an individual SQL Server database and optionally filter the records to be imported using a query. In addition, you can modify the document structure by specifying a nesting separator (more on that in a moment).

The format of the connection string is the standard SQL connection string format.

> **NOTE**
> Use the Verify command to ensure that the SQL Server instance specified in the connection string field can be accessed.

The nesting separator property is used to create hierarchical relationships (sub-documents) during import. Consider the following SQL query:

```
select CAST(BusinessEntityID AS varchar) as Id, Name, AddressType as [Address.AddressType], AddressLine1 as [Address.AddressLine1], City as [Address.Location.City],
StateProvinceName as [Address.Location.StateProvinceName], PostalCode as [Address.PostalCode], CountryRegionName as [Address.CountryRegionName] from
Sales.vStoreWithAddresses WHERE AddressType='Main Office'
```

Which returns the following (partial) results:

	Id	Name	Address.AddressType	Address.AddressLine1	Address.Location.City	Address.Location.StateProvinceName	Address.PostalCode	Address.CountryRegionName
1	956	Finer Sales and Service	Main Office	#500-75 O'Connor Street	Ottawa	Ontario	K4B 1S2	Canada
2	780	Finer Riding Supplies	Main Office	#9900 2700 Production Way	Burnaby	British Columbia	V5A 4X1	Canada
3	1012	Stylish Department Stores	Main Office	1 Corporate Center Drive	Miami	Florida	33127	United States
4	482	Favorite Toy Distributor	Main Office	1, place de la République	Paris	Seine (Paris)	75017	France
5	1338	Sports Sales and Rental	Main Office	100 Fifth Drive	Millington	Tennessee	38054	United States
6	1424	Closeout Boutique	Main Office	1050 Oak Street	Seattle	Washington	98104	United States
7	1274	Self-Contained Cycle Parts Company	Main Office	12, rue des Grands Champs	Verrieres Le Buisson	Essonne	91370	France
8	1958	Ultimate Bicycle Company	Main Office	12, rue Lafayette	Morangis	Essonne	91420	France
9	1110	Local Sales and Rental	Main Office	1200 First Ave.	Joliet	Illinois	60433	United States
10	1262	Roadway Bicycle Supply	Main Office	121, rue de Varenne	Courbevoie	Hauts de Seine	92400	France

Note the aliases such as Address.AddressType and Address.Location.StateProvinceName. By specifying a nesting separator of '.', the import tool creates Address and Address.Location subdocuments during the import. Here is an example of a resulting document in Azure Cosmos DB:

{ "id": "956", "Name": "Finer Sales and Service", "Address": { "AddressType": "Main Office", "AddressLine1": "#500-75 O'Connor Street", "Location": { "City": "Ottawa", "StateProvinceName": "Ontario" }, "PostalCode": "K4B 1S2", "CountryRegionName": "Canada" } }

Here are some command-line samples to import from SQL Server:

```
#Import records from SQL which match a query
dt.exe /s:SQL /s.ConnectionString:"Data Source=<server>;Initial Catalog=AdventureWorks;User Id=advworks;Password=<password>;" /s.Query:"select CAST(BusinessEntityID AS
varchar) as Id, * from Sales.vStoreWithAddresses WHERE AddressType='Main Office'" /t:DocumentDBBulk /t.ConnectionString:" AccountEndpoint=<CosmosDB Endpoint>;AccountKey=
<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:Stores /t.IdField:Id /t.CollectionThroughput:2500

#Import records from sql which match a query and create hierarchical relationships
dt.exe /s:SQL /s.ConnectionString:"Data Source=<server>;Initial Catalog=AdventureWorks;User Id=advworks;Password=<password>;" /s.Query:"select CAST(BusinessEntityID AS
varchar) as Id, Name, AddressType as [Address.AddressType], AddressLine1 as [Address.AddressLine1], City as [Address.Location.City], StateProvinceName as
[Address.Location.StateProvinceName], PostalCode as [Address.PostalCode], CountryRegionName as [Address.CountryRegionName] from Sales.vStoreWithAddresses WHERE
AddressType='Main Office'" /s.NestingSeparator:. /t:DocumentDBBulk /t.ConnectionString:" AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB
Database>;" /t.Collection:StoresSub /t.IdField:Id /t.CollectionThroughput:2500
```

Import CSV files and convert CSV to JSON

The CSV file source importer option enables you to import one or more CSV files. When adding folders that have CSV files for import, you have the option of recursively searching for files in subfolders.

Similar to the SQL source, the nesting separator property may be used to create hierarchical relationships (sub-documents) during import. Consider the following CSV header row and data rows:

```
DomainInfo.Domain_Name,DomainInfo.Domain_Name_Address,Federal Agency,RedirectInfo.Redirecting,RedirectInfo.Redirect_Destination
ACUS.GOV,http://www.ACUS.GOV,Administrative Conference of the United States,0,
ACHP.GOV,http://www.ACHP.GOV,Advisory Council on Historic Preservation,0,
PRESERVEAMERICA.GOV,http://www.PRESERVEAMERICA.GOV,Advisory Council on Historic Preservation,0,
ADF.GOV,http://www.ADF.GOV,African Development Foundation,0,
```

Note the aliases such as DomainInfo.Domain_Name and RedirectInfo.Redirecting. By specifying a nesting separator of '.', the import tool will create DomainInfo and RedirectInfo subdocuments during the import. Here is an example of a resulting document in Azure Cosmos DB:

{ "DomainInfo": { "Domain_Name": "ACUS.GOV", "Domain_Name_Address": "https://www.ACUS.GOV" }, "Federal Agency": "Administrative Conference of the United States", "RedirectInfo": { "Redirecting": "0", "Redirect_Destination": "" }, "id": "9cc565c5-ebcd-1c03-ebd3-cc3e2ecd814d" }

The import tool tries to infer type information for unquoted values in CSV files (quoted values are always treated as strings). Types are identified in the following order: number, datetime, boolean.

There are two other things to note about CSV import:

1. By default, unquoted values are always trimmed for tabs and spaces, while quoted values are preserved as-is. This behavior can be overridden with the Trim quoted values checkbox or the /s.TrimQuoted command-line option.
2. By default, an unquoted null is treated as a null value. This behavior can be overridden (that is, treat an unquoted null as a "null" string) with the Treat unquoted NULL as string checkbox or the /s.NoUnquotedNulls command-line option.

Here is a command-line sample for CSV import:

```
dt.exe /s:CsvFile /s.Files:.\Employees.csv /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB
Database>;" /t.Collection:Employees /t.IdField:EntityID /t.CollectionThroughput:2500
```

Import from Azure Table storage

The Azure Table storage source importer option allows you to import from an individual Azure Table storage table. Optionally, you can filter the table entities to be imported.

You may output data that was imported from Azure Table Storage to Azure Cosmos DB tables and entities for use with the Table API. Imported data can also be output to collections and documents for use with the SQL API. However, Table API is only available as a target in the command-line utility. You can't export to Table API by using the Data Migration tool user interface. For more information, see Import data for use with the Azure Cosmos DB Table API.

The format of the Azure Table storage connection string is:

```
DefaultEndpointsProtocol=<protocol>;AccountName=<Account Name>;AccountKey=<Account Key>;
```

> **NOTE**
> Use the Verify command to ensure that the Azure Table storage instance specified in the connection string field can be accessed.

Enter the name of the Azure table from to import from. You may optionally specify a filter.

The Azure Table storage source importer option has the following additional options:

1. Include Internal Fields
   a. All - Include all internal fields (PartitionKey, RowKey, and Timestamp)
   b. None - Exclude all internal fields
   c. RowKey - Only include the RowKey field
2. Select Columns
   a. Azure Table storage filters don't support projections. If you want to only import specific Azure Table entity properties, add them to the Select Columns list. All other entity properties are ignored.

Here is a command-line sample to import from Azure Table storage:

```
dt.exe /s:AzureTable /s.ConnectionString:"DefaultEndpointsProtocol=https;AccountName=<Account Name>;AccountKey=<Account Key>" /s.Table:metrics /s.InternalFields:All
/s.Filter:"PartitionKey eq 'Partition1' and RowKey gt '00001'" /s.Projection:ObjectCount;ObjectSize  /t:DocumentDBBulk /t.ConnectionString:" AccountEndpoint=<CosmosDB
Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:metrics /t.CollectionThroughput:2500
```

Import from Amazon DynamoDB

The Amazon DynamoDB source importer option allows you to import from a single Amazon DynamoDB table. It can optionally filter the entities to be imported. Several templates are provided so that setting up an import is as easy as possible.

The format of the Amazon DynamoDB connection string is:

```
ServiceURL=<Service Address>;AccessKey=<Access Key>;SecretKey=<Secret Key>;
```

> **NOTE**
> Use the Verify command to ensure that the Amazon DynamoDB instance specified in the connection string field can be accessed.

Here is a command-line sample to import from Amazon DynamoDB:

```
dt.exe /s:DynamoDB /s.ConnectionString:ServiceURL=https://dynamodb.us-east-1.amazonaws.com;AccessKey=<accessKey>;SecretKey=<secretKey> /s.Request:"{   """TableName""":
"""ProductCatalog""" }" /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<Azure Cosmos DB Endpoint>;AccountKey=<Azure Cosmos DB Key>;Database=<Azure Cosmos
database>;" /t.Collection:catalogCollection /t.CollectionThroughput:2500
```

Import from Azure Blob storage

The JSON file, MongoDB export file, and CSV file source importer options allow you to import one or more files from Azure Blob storage. After specifying a Blob container URL and Account Key, provide a regular expression to select the file(s) to import.

Here is command-line sample to import JSON files from Azure Blob storage:

```
dt.exe /s:JsonFile /s.Files:"blobs://<account key>@account.blob.core.windows.net:443/importcontainer/.*" /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB
Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:doctest
```

Import from a SQL API collection

The Azure Cosmos DB source importer option allows you to import data from one or more Azure Cosmos containers and optionally filter documents using a query.

The format of the Azure Cosmos DB connection string is:

```
AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;
```

You can retrieve the Azure Cosmos DB account connection string from the Keys page of the Azure portal, as described in How to manage an Azure Cosmos DB account. However, the name of the database needs to be appended to the connection string in the following format:

```
Database=<CosmosDB Database>;
```

> **NOTE**
> Use the Verify command to ensure that the Azure Cosmos DB instance specified in the connection string field can be accessed.

To import from a single Azure Cosmos container, enter the name of the collection to import data from. To import from more than one Azure Cosmos container, provide a regular expression to match one or more collection names (for example, collection01 | collection02 | collection03). You may optionally specify, or provide a file for, a query to both filter and shape the data that you're importing.

> **NOTE**
> Since the collection field accepts regular expressions, if you're importing from a single collection whose name has regular expression characters, then those characters must be escaped accordingly.

The Azure Cosmos DB source importer option has the following advanced options:

1. Include Internal Fields: Specifies whether or not to include Azure Cosmos DB document system properties in the export (for example, _rid, _ts).
2. Number of Retries on Failure: Specifies the number of times to retry the connection to Azure Cosmos DB in case of transient failures (for example, network connectivity interruption).
3. Retry Interval: Specifies how long to wait between retrying the connection to Azure Cosmos DB in case of transient failures (for example, network connectivity interruption).
4. Connection Mode: Specifies the connection mode to use with Azure Cosmos DB. The available choices are DirectTcp, DirectHttps, and Gateway. The direct connection modes are faster, while the gateway mode is more firewall friendly as it only uses port 443.

TIP

The import tool defaults to connection mode DirectTcp. If you experience firewall issues, switch to connection mode Gateway, as it only requires port 443.

Here are some command-line samples to import from Azure Cosmos DB:

```
#Migrate data from one Azure Cosmos container to another Azure Cosmos containers
dt.exe /s:DocumentDB /s.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /s.Collection:TEColl
/t:DocumentDBBulk /t.ConnectionString:" AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:TESessions
/t.CollectionThroughput:2500

#Migrate data from more than one Azure Cosmos container to a single Azure Cosmos container
dt.exe /s:DocumentDB /s.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;"
/s.Collection:comp1|comp2|comp3|comp4 /t:DocumentDBBulk /t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;"
/t.Collection:singleCollection /t.CollectionThroughput:2500

#Export an Azure Cosmos container to a JSON file
dt.exe /s:DocumentDB /s.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /s.Collection:StoresSub
/t:JsonFile /t.File:StoresExport.json /t.Overwrite
```

TIP

The Azure Cosmos DB Data Import Tool also supports import of data from the Azure Cosmos DB Emulator. When importing data from a local emulator, set the endpoint to `https://localhost:<port>`.

Import from HBase

The HBase source importer option allows you to import data from an HBase table and optionally filter the data. Several templates are provided so that setting up an import is as easy as possible.

The format of the HBase Stargate connection string is:

```
ServiceURL=<server-address>;Username=<username>;Password=<password>
```

> **NOTE**
> Use the Verify command to ensure that the HBase instance specified in the connection string field can be accessed.

Here is a command-line sample to import from HBase:

```
dt.exe /s:HBase /s.ConnectionString:ServiceURL=<server-address>;Username=<username>;Password=<password> /s.Table:Contacts /t:DocumentDBBulk
/t.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;" /t.Collection:hbaseimport
```

Import to the SQL API (Bulk Import)

The Azure Cosmos DB Bulk importer allows you to import from any of the available source options, using an Azure Cosmos DB stored procedure for efficiency. The tool supports import to one single-partitioned Azure Cosmos container. It also supports sharded import whereby data is partitioned across more than one single-partitioned Azure Cosmos container. For more information about partitioning data, see Partitioning and scaling in Azure Cosmos DB. The tool creates, executes, and then deletes the stored procedure from the target collection(s).

The format of the Azure Cosmos DB connection string is:

```
AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;
```

The Azure Cosmos DB account connection string can be retrieved from the Keys page of the Azure portal, as described in How to manage an Azure Cosmos DB account, however the name of the database needs to be appended to the connection string in the following format:

```
Database=<CosmosDB Database>;
```

> **NOTE**
> Use the Verify command to ensure that the Azure Cosmos DB instance specified in the connection string field can be accessed.

To import to a single collection, enter the name of the collection to import data from and click the Add button. To import to more than one collection, either enter each collection name individually or use the following syntax to specify more than one collection: *collection_prefix*[start index - end index]. When specifying more than one collection using the aforementioned syntax, keep the following guidelines in mind:

1. Only integer range name patterns are supported. For example, specifying collection[0-3] creates the following collections: collection0, collection1, collection2, collection3.
2. You can use an abbreviated syntax: collection[3] creates the same set of collections mentioned in step 1.
3. More than one substitution can be provided. For example, collection[0-1] [0-9] generates 20 collection names with leading zeros (collection01, ..02, ..03).

Once the collection name(s) have been specified, choose the desired throughput of the collection(s) (400 RUs to 10,000 RUs). For best import performance, choose a higher throughput. For more information about performance levels, see Performance levels in Azure Cosmos DB.

> **NOTE**
> The performance throughput setting only applies to collection creation. If the specified collection already exists, its throughput won't be modified.

When you import to more than one collection, the import tool supports hash-based sharding. In this scenario, specify the document property you wish to use as the Partition Key. (If Partition Key is left blank, documents are sharded randomly across the target collections.)

You may optionally specify which field in the import source should be used as the Azure Cosmos DB document ID property during the import. If documents don't have this property, then the import tool generates a GUID as the ID property value.

There are a number of advanced options available during import. First, while the tool includes a default bulk import stored procedure (BulkInsert.js), you may choose to specify your own import stored procedure:

Additionally, when importing date types (for example, from SQL Server or MongoDB), you can choose between three import options:

- String: Persist as a string value
- Epoch: Persist as an Epoch number value
- Both: Persist both string and Epoch number values. This option creates a subdocument, for example: "date_joined": { "Value": "2013-10-21T21:17:25.2410000Z", "Epoch": 1382390245 }

The Azure Cosmos DB Bulk importer has the following additional advanced options:

1. Batch Size: The tool defaults to a batch size of 50. If the documents to be imported are large, consider lowering the batch size. Conversely, if the documents to be imported are small, consider raising the batch size.
2. Max Script Size (bytes): The tool defaults to a max script size of 512 KB.
3. Disable Automatic Id Generation: If every document to be imported has an ID field, then selecting this option can increase performance. Documents missing a unique ID

field aren't imported.

4. Update Existing Documents: The tool defaults to not replacing existing documents with ID conflicts. Selecting this option allows overwriting existing documents with matching IDs. This feature is useful for scheduled data migrations that update existing documents.
5. Number of Retries on Failure: Specifies how often to retry the connection to Azure Cosmos DB during transient failures (for example, network connectivity interruption).
6. Retry Interval: Specifies how long to wait between retrying the connection to Azure Cosmos DB in case of transient failures (for example, network connectivity interruption).
7. Connection Mode: Specifies the connection mode to use with Azure Cosmos DB. The available choices are DirectTcp, DirectHttps, and Gateway. The direct connection modes are faster, while the gateway mode is more firewall friendly as it only uses port 443.

TIP

The import tool defaults to connection mode DirectTcp. If you experience firewall issues, switch to connection mode Gateway, as it only requires port 443.

Import to the SQL API (Sequential Record Import)

The Azure Cosmos DB sequential record importer allows you to import from an available source option on a record-by-record basis. You might choose this option if you're importing to an existing collection that has reached its quota of stored procedures. The tool supports import to a single (both single-partition and multi-partition) Azure Cosmos container. It also supports sharded import whereby data is partitioned across more than one single-partition or multi-partition Azure Cosmos container. For more information about partitioning data, see Partitioning and scaling in Azure Cosmos DB.

The format of the Azure Cosmos DB connection string is:

```
AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB Database>;
```

You can retrieve the connection string for the Azure Cosmos DB account from the Keys page of the Azure portal, as described in How to manage an Azure Cosmos DB account. However, the name of the database needs to be appended to the connection string in the following format:

```
Database=<Azure Cosmos database>;
```

> **NOTE**
> Use the Verify command to ensure that the Azure Cosmos DB instance specified in the connection string field can be accessed.

To import to a single collection, enter the name of the collection to import data into, and then click the Add button. To import to more than one collection, enter each collection name individually. You may also use the following syntax to specify more than one collection: *collection_prefix*[start index - end index]. When specifying more than one collection via the aforementioned syntax, keep the following guidelines in mind:

1. Only integer range name patterns are supported. For example, specifying collection[0-3] creates the following collections: collection0, collection1, collection2, collection3.
2. You can use an abbreviated syntax: collection[3] creates the same set of collections mentioned in step 1.
3. More than one substitution can be provided. For example, collection[0-1] [0-9] creates 20 collection names with leading zeros (collection01, ..02, ..03).

Once the collection name(s) have been specified, choose the desired throughput of the collection(s) (400 RUs to 250,000 RUs). For best import performance, choose a higher throughput. For more information about performance levels, see Performance levels in Azure Cosmos DB. Any import to collections with throughput >10,000 RUs require a partition key. If you choose to have more than 250,000 RUs, you need to file a request in the portal to have your account increased.

> **NOTE**
> The throughput setting only applies to collection or database creation. If the specified collection already exists, its throughput won't be modified.

When importing to more than one collection, the import tool supports hash-based sharding. In this scenario, specify the document property you wish to use as the Partition Key. (If Partition Key is left blank, documents are sharded randomly across the target collections.)

You may optionally specify which field in the import source should be used as the Azure Cosmos DB document ID property during the import. (If documents don't have this property, then the import tool generates a GUID as the ID property value.)

There are a number of advanced options available during import. First, when importing date types (for example, from SQL Server or MongoDB), you can choose between three import options:

- String: Persist as a string value
- Epoch: Persist as an Epoch number value
- Both: Persist both string and Epoch number values. This option creates a subdocument, for example: "date_joined": { "Value": "2013-10-21T21:17:25.2410000Z", "Epoch": 1382390245 }

The Azure Cosmos DB - Sequential record importer has the following additional advanced options:

1. Number of Parallel Requests: The tool defaults to two parallel requests. If the documents to be imported are small, consider raising the number of parallel requests. If this number is raised too much, the import may experience rate limiting.
2. Disable Automatic Id Generation: If every document to be imported has an ID field, then selecting this option can increase performance. Documents missing a unique ID field aren't imported.
3. Update Existing Documents: The tool defaults to not replacing existing documents with ID conflicts. Selecting this option allows overwriting existing documents with matching IDs. This feature is useful for scheduled data migrations that update existing documents.
4. Number of Retries on Failure: Specifies how often to retry the connection to Azure Cosmos DB during transient failures (for example, network connectivity interruption).
5. Retry Interval: Specifies how long to wait between retrying the connection to Azure Cosmos DB during transient failures (for example, network connectivity interruption).
6. Connection Mode: Specifies the connection mode to use with Azure Cosmos DB. The available choices are DirectTcp, DirectHttps, and Gateway. The direct connection modes are faster, while the gateway mode is more firewall friendly as it only uses port 443.

TIP

The import tool defaults to connection mode DirectTcp. If you experience firewall issues, switch to connection mode Gateway, as it only requires port 443.

Specify an indexing policy

When you allow the migration tool to create Azure Cosmos DB SQL API collections during import, you can specify the indexing policy of the collections. In the advanced options section of the Azure Cosmos DB Bulk import and Azure Cosmos DB Sequential record options, navigate to the Indexing Policy section.

Using the Indexing Policy advanced option, you can select an indexing policy file, manually enter an indexing policy, or select from a set of default templates (by right-clicking in the indexing policy textbox).

The policy templates the tool provides are:

- Default. This policy is best when you perform equality queries against strings. It also works if you use ORDER BY, range, and equality queries for numbers. This policy has a lower index storage overhead than Range.
- Range. This policy is best when you use ORDER BY, range, and equality queries on both numbers and strings. This policy has a higher index storage overhead than Default or Hash.

> **NOTE**
> If you don't specify an indexing policy, then the default policy is applied. For more information about indexing policies, see Azure Cosmos DB indexing policies.

Export to JSON file

The Azure Cosmos DB JSON exporter allows you to export any of the available source options to a JSON file that has an array of JSON documents. The tool handles the export for you. Alternatively, you can choose to view the resulting migration command and run the command yourself. The resulting JSON file may be stored locally or in Azure Blob storage.

You may optionally choose to prettify the resulting JSON. This action will increase the size of the resulting document while making the contents more human readable.

- Standard JSON export

```
[{"id":"Sample","Title":"About Paris","Language":{"Name":"English"},"Author":{"Name":"Don","Location":{"City":"Paris","Country":"France"}},"Content":"Don's
document in Azure Cosmos DB is a valid JSON document as defined by the JSON spec.","PageViews":10000,"Topics":[{"Title":"History of Paris"},{"Title":"Places to
see in Paris"}]}]
```

- Prettified JSON export

```
[
 {
"id": "Sample",
"Title": "About Paris",
"Language": {
  "Name": "English"
},
"Author": {
  "Name": "Don",
  "Location": {
    "City": "Paris",
    "Country": "France"
  }
},
"Content": "Don's document in Azure Cosmos DB is a valid JSON document as defined by the JSON spec.",
"PageViews": 10000,
"Topics": [
  {
    "Title": "History of Paris"
  },
  {
    "Title": "Places to see in Paris"
  }
]
}]
```

Here is a command-line sample to export the JSON file to Azure Blob storage:

```
dt.exe /ErrorDetails:All /s:DocumentDB /s.ConnectionString:"AccountEndpoint=<CosmosDB Endpoint>;AccountKey=<CosmosDB Key>;Database=<CosmosDB database_name>"
/s.Collection:<CosmosDB collection_name>
/t:JsonFile /t.File:"blobs://<Storage account key>@<Storage account name>.blob.core.windows.net:443/<Container_name>/<Blob_name>"
/t.Overwrite
```

Advanced configuration

In the Advanced configuration screen, specify the location of the log file to which you would like any errors written. The following rules apply to this page:

1. If a file name isn't provided, then all errors are returned on the Results page.
2. If a file name is provided without a directory, then the file is created (or overwritten) in the current environment directory.
3. If you select an existing file, then the file is overwritten, there's no append option.
4. Then, choose whether to log all, critical, or no error messages. Finally, decide how frequently the on-screen transfer message is updated with its progress.

Confirm import settings and view command line

1. After you specify the source information, target information, and advanced configuration, review the migration summary and view or copy the resulting migration command if you want. (Copying the command is useful to automate import operations.)

2. Once you're satisfied with your source and target options, click **Import**. The elapsed time, transferred count, and failure information (if you didn't provide a file name in the Advanced configuration) update as the import is in process. Once complete, you can export the results (for example, to deal with any import failures).

3. You may also start a new import by either resetting all values or keeping the existing settings. (For example, you may choose to keep connection string information, source and target choice, and more.)

Next steps

In this tutorial, you've done the following tasks:

- Installed the Data Migration tool
- Imported data from different data sources
- Exported from Azure Cosmos DB to JSON

You can now proceed to the next tutorial and learn how to query data using Azure Cosmos DB.

How to query data?

Bulk import data to Azure Cosmos DB SQL API account by using the .NET SDK

12/4/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API

This tutorial shows how to build a .NET console application that optimizes provisioned throughput (RU/s) required to import data to Azure Cosmos DB. In this article, you will read data from a sample data source and import it into an Azure Cosmos container. This tutorial uses Version 3.0+ of the Azure Cosmos DB .NET SDK, which can be targeted to .NET Framework or .NET Core.

This tutorial covers:

- Creating an Azure Cosmos account
- Configuring your project
- Connecting to an Azure Cosmos account with bulk support enabled
- Perform a data import through concurrent create operations

Prerequisites

Before following the instructions in this article, make sure that you have the following resources:

- An active Azure account. If you don't have an Azure subscription, create a free account before you begin.

  You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

- NET Core 3 SDK. You can verify which version is available in your environment by running `dotnet --version`.

Step 1: Create an Azure Cosmos DB account

Create an Azure Cosmos DB SQL API account from the Azure portal or you can create the account by using the Azure Cosmos DB Emulator.

Step 2: Set up your .NET project

Open the Windows command prompt or a Terminal window from your local computer. You will run all the commands in the next sections from the command prompt or terminal. Run the following dotnet new command to create a new app with the name *bulk-import-demo*. The `--langVersion` parameter sets the *LangVersion* property in the created project file.

```
dotnet new console –langVersion:8 -n bulk-import-demo
```

Change your directory to the newly created app folder. You can build the application with:

```
cd bulk-import-demo
dotnet build
```

The expected output from the build should look something like this:

```
Restore completed in 100.37 ms for C:\Users\user1\Downloads\CosmosDB_Samples\bulk-import-demo\bulk-import-demo.csproj.
  bulk -> C:\Users\user1\Downloads\CosmosDB_Samples\bulk-import-demo \bin\Debug\netcoreapp2.2\bulk-import-demo.dll

Build succeeded.
    0 Warning(s)
    0 Error(s)

Time Elapsed 00:00:34.17
```

Step 3: Add the Azure Cosmos DB package

While still in the application directory, install the Azure Cosmos DB client library for .NET Core by using the dotnet add package command.

```
dotnet add package Microsoft.Azure.Cosmos
```

Step 4: Get your Azure Cosmos account credentials

The sample application needs to authenticate to your Azure Cosmos account. To authenticate, you should pass the Azure Cosmos account credentials to the application. Get your Azure Cosmos account credentials by following these steps:

1. Sign in to the Azure portal.
2. Navigate to your Azure Cosmos account.
3. Open the **Keys** pane and copy the **URI** and **PRIMARY KEY** of your account.

If you are using the Azure Cosmos DB Emulator, obtain the emulator credentials from this article.

Step 5: Initialize the CosmosClient object with bulk execution support

Open the generated `Program.cs` file in a code editor. You will create a new instance of CosmosClient with bulk execution enabled and use it to do operations against Azure Cosmos DB.

Let's start by overwriting the default `Main` method and defining the global variables. These global variables will include the endpoint and authorization keys, the name of the database, container that you will create, and the number of items that you will be inserting in bulk. Make sure to replace the endpointURL and authorization key values according to your environment.

```
using System;
using System.Collections.Generic;
using System.Diagnostics;
using System.IO;
using System.Text.Json;
using System.Threading.Tasks;
using Microsoft.Azure.Cosmos;

public class Program
{
     private const string EndpointUrl = "https://<your-account>.documents.azure.com:443/";
     private const string AuthorizationKey = "<your-account-key>";
     private const string DatabaseName = "bulk-tutorial";
     private const string ContainerName = "items";
     private const int ItemsToInsert = 300000;

     static async Task Main(string[] args)
     {

     }
}
```

Inside the `Main` method, add the following code to initialize the CosmosClient object:

```
CosmosClient cosmosClient = new CosmosClient(EndpointUrl, AuthorizationKey, new CosmosClientOptions() {
AllowBulkExecution = true });
```

After the bulk execution is enabled, the CosmosClient internally groups concurrent operations into single service calls. This way it optimizes the throughput utilization by distributing service calls across partitions, and finally assigning individual results to the original callers.

You can then create a container to store all our items. Define `/pk` as the partition key, 50000 RU/s as provisioned throughput, and a custom indexing policy that will exclude all fields to optimize the write throughput. Add the following code after the CosmosClient initialization statement:

```
Database database = await cosmosClient.CreateDatabaseIfNotExistsAsync(Program.DatabaseName);

await database.DefineContainer(Program.ContainerName, "/pk")
        .WithIndexingPolicy()
            .WithIndexingMode(IndexingMode.Consistent)
            .WithIncludedPaths()
                .Attach()
            .WithExcludedPaths()
                .Path("/*")
                .Attach()
        .Attach()
    .CreateAsync(50000);
```

Step 6: Populate a list of concurrent tasks

To take advantage of the bulk execution support, create a list of asynchronous tasks based on the source of data and the operations you want to perform, and use `Task.WhenAll` to execute them concurrently. Let's start by using "Bogus" data to generate a list of items from our data model. In a real-world application, the items would come from your desired data source.

First, add the Bogus package to the solution by using the dotnet add package command.

```
dotnet add package Bogus
```

Define the definition of the items that you want to save. You need to define the `Item` class within the `Program.cs` file:

```
public class Item
{
    public string id {get;set;}
    public string pk {get;set;}

    public string username{get;set;}
}
```

Next, create a helper function inside the `Program` class. This helper function will get the number of items you defined to insert and generates random data:

```
private static IReadOnlyCollection<Item> GetItemsToInsert()
{
    return new Bogus.Faker<Item>()
    .StrictMode(true)
    //Generate item
    .RuleFor(o => o.id, f => Guid.NewGuid().ToString()) //id
    .RuleFor(o => o.username, f => f.Internet.UserName())
    .RuleFor(o => o.pk, (f, o) => o.id) //partitionkey
    .Generate(ItemsToInsert);
}
```

Read the items and serialize them into stream instances by using the `System.Text.Json` class. Because of the nature of the autogenerated data, you are serializing the data as streams. You can also use the item instance directly, but by converting them to streams, you can leverage the performance of stream APIs in the CosmosClient. Typically you can use the data directly as long as you know the partition key.

To convert the data to stream instances, within the `Main` method, add the following code right after creating the container:

```
Dictionary<PartitionKey, Stream> itemsToInsert = new Dictionary<PartitionKey, Stream>(ItemsToInsert);
foreach (Item item in Program.GetItemsToInsert())
{
    MemoryStream stream = new MemoryStream();
    await JsonSerializer.SerializeAsync(stream, item);
    itemsToInsert.Add(new PartitionKey(item.pk), stream);
}
```

Next use the data streams to create concurrent tasks and populate the task list to insert the items into the container. To perform this operation, add the following code to the `Program` class:

```
Container container = database.GetContainer(ContainerName);
List<Task> tasks = new List<Task>(ItemsToInsert);
foreach (KeyValuePair<PartitionKey, Stream> item in itemsToInsert)
{
    tasks.Add(container.CreateItemStreamAsync(item.Value, item.Key)
        .ContinueWith((Task<ResponseMessage> task) =>
        {
            using (ResponseMessage response = task.Result)
            {
                if (!response.IsSuccessStatusCode)
                {
                    Console.WriteLine($"Received {response.StatusCode} ({response.ErrorMessage}).");
                }
            }
        }));
}

// Wait until all are done
await Task.WhenAll(tasks);
```

All these concurrent point operations will be executed together (that is in bulk) as described in the introduction section.

Step 7: Run the sample

In order to run the sample, you can do it simply by the `dotnet` command:

```
dotnet run
```

Get the complete sample

If you didn't have time to complete the steps in this tutorial, or just want to download the code samples, you can get it from GitHub.

After cloning the project, make sure to update the desired credentials inside Program.cs.

The sample can be run by changing to the repository directory and using `dotnet`:

```
cd cosmos-dotnet-bulk-import-throughput-optimizer
dotnet run
```

Next steps

In this tutorial, you've done the following steps:

- Creating an Azure Cosmos account
- Configuring your project
- Connecting to an Azure Cosmos account with bulk support enabled
- Perform a data import through concurrent create operations

You can now proceed to the next tutorial:

Query Azure Cosmos DB by using the SQL API

Tutorial: Query Azure Cosmos DB by using the SQL API

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The Azure Cosmos DB SQL API supports querying documents using SQL. This article provides a sample document and two sample SQL queries and results.

This article covers the following tasks:

- Querying data with SQL

Sample document

The SQL queries in this article use the following sample document.

```
{
  "id": "WakefieldFamily",
  "parents": [
      { "familyName": "Wakefield", "givenName": "Robin" },
      { "familyName": "Miller", "givenName": "Ben" }
  ],
  "children": [
      {
        "familyName": "Merriam",
        "givenName": "Jesse",
        "gender": "female", "grade": 1,
        "pets": [
            { "givenName": "Goofy" },
            { "givenName": "Shadow" }
        ]
      },
      {
        "familyName": "Miller",
         "givenName": "Lisa",
         "gender": "female",
         "grade": 8 }
  ],
  "address": { "state": "NY", "county": "Manhattan", "city": "NY" },
  "creationDate": 1431620462,
  "isRegistered": false
}
```

Where can I run SQL queries?

You can run queries using the Data Explorer in the Azure portal, via the REST API and SDKs, and even the Query playground, which runs queries on an existing set of sample data.

For more information about SQL queries, see:

- SQL query and SQL syntax

Prerequisites

This tutorial assumes you have an Azure Cosmos DB account and collection. Don't have any of those resources? Complete the 5-minute quickstart.

Example query 1

Given the sample family document above, following SQL query returns the documents where the ID field matches `WakefieldFamily`. Since it's a `SELECT *` statement, the output of the query is the complete JSON document:

Query

```
SELECT *
FROM Families f
WHERE f.id = "WakefieldFamily"
```

Results

```
{
  "id": "WakefieldFamily",
  "parents": [
      { "familyName": "Wakefield", "givenName": "Robin" },
      { "familyName": "Miller", "givenName": "Ben" }
  ],
  "children": [
      {
        "familyName": "Merriam",
        "givenName": "Jesse",
        "gender": "female", "grade": 1,
        "pets": [
            { "givenName": "Goofy" },
            { "givenName": "Shadow" }
        ]
      },
      {
        "familyName": "Miller",
         "givenName": "Lisa",
         "gender": "female",
         "grade": 8 }
  ],
  "address": { "state": "NY", "county": "Manhattan", "city": "NY" },
  "creationDate": 1431620462,
  "isRegistered": false
}
```

Example query 2

The next query returns all the given names of children in the family whose ID matches `WakefieldFamily`.

Query

```
SELECT c.givenName
FROM Families f
JOIN c IN f.children
WHERE f.id = 'WakefieldFamily'
```

Results

```
[
    {
        "givenName": "Jesse"
    },
    {
        "givenName": "Lisa"
    }
]
```

Next steps

In this tutorial, you've done the following tasks:

- Learned how to query using SQL

You can now proceed to the next tutorial to learn how to distribute your data globally.

Distribute your data globally

Tutorial: Create a notebook in Azure Cosmos DB to analyze and visualize the data

12/4/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes how to use built-in Jupyter notebooks to import sample retail data to Azure Cosmos DB. You will see how to use the SQL and Azure Cosmos DB magic commands to run queries, analyze the data, and visualize the results.

Prerequisites

- Enable notebooks support while creating the Azure Cosmos account

Create the resources and import data

In this section, you will create the Azure Cosmos database, container, and import the retail data to the container.

1. Navigate to your Azure Cosmos account and open the **Data Explorer.**
2. Go to the **Notebooks** tab, select ... next to **My Notebooks** and create a **New Notebook**. Select **Python 3** as the default Kernel.

3. After a new notebook is created, you can rename it to something like **VisualizeRetailData.ipynb.**
4. Next you will create a database named "RetailDemo" and a container named "WebsiteData" to store the retail data. You can use /CartID as the partition key. Copy and paste the following code to a new cell in your notebook and run it:

```
import azure.cosmos
from azure.cosmos.partition_key import PartitionKey

database = cosmos_client.create_database_if_not_exists('RetailDemo')
print('Database RetailDemo created')

container = database.create_container_if_not_exists(id='WebsiteData',
partition_key=PartitionKey(path='/CartID'))
print('Container WebsiteData created')
```

To run a cell, select `Shift + Enter` Or select the cell and choose **Run Active Cell** option at the data explorer navigation bar.

The database and container are created in your current Azure Cosmos account. The container is provisioned with 400 RU/s. You will see the following output after the database and container is created.

```
Database RetailDemo created
Container WebsiteData created
```

You can also refresh the **Data** tab and see the newly created resources:

5. Next you will import the sample retail data into Azure Cosmos container. Here is the format of an item from the retail data:

```
{
   "CartID":5399,
   "Action":"Viewed",
   "Item":"Cosmos T-shirt",
   "Price":350,
   "UserName":"Demo.User10",
   "Country":"Iceland",
   "EventDate":"2015-06-25T00:00:00",
   "Year":2015,"Latitude":-66.8673,
   "Longitude":-29.8214,
   "Address":"852 Modesto Loop, Port Ola, Iceland",
   "id":"00ffd39c-7e98-4451-9b91-b2bcf2f9a32d"
}
```

For the tutorial purpose, the sample retail data is stored in the Azure blob storage. You can import it to the Azure Cosmos container by pasting the following code into a new cell. You can confirm that the data is successfully imported by running a query to select the number of items.

```
# Read data from storage
import urllib.request, json

with
urllib.request.urlopen("https://cosmosnotebooksdata.blob.core.windows.net/notebookdata/websiteData.json"
) as url:
   data = json.loads(url.read().decode())

print("Importing data. This will take a few minutes...\n")

for event in data:
 try:
    container.upsert_item(body=event)
 except errors.CosmosHttpResponseError as e:
    raise

## Run a query against the container to see number of documents
query = 'SELECT VALUE COUNT(1) FROM c'
result = list(container.query_items(query, enable_cross_partition_query=True))

print('Container with id \'{0}\' contains \'{1}\' items'.format(container.id, result[0]))
```

When you run the previous query, it returns the following output:

```
Importing data. This will take a few minutes...

Container with id 'WebsiteData' contains '2654' items
```

Get your data into a DataFrame

Before running queries to analyze the data, you can read the data from container to a Pandas DataFrame for analysis. Use the following sql magic command to read the data into a DataFrame:

```
%%sql --database {database_id} --container {container_id} --output outputDataframeVar
{Query text}
```

To learn more, see the built-in notebook commands and features in Azure Cosmos DB article. You will run the query- `SELECT c.Action, c.Price as ItemRevenue, c.Country, c.Item FROM c`. The results will be saved into a Pandas DataFrame named df_cosmos. Paste the following command in a new notebook cell and run it:

```
%%sql --database RetailDemo --container WebsiteData --output df_cosmos
SELECT c.Action, c.Price as ItemRevenue, c.Country, c.Item FROM c
```

In a new notebook cell, run the following code to read the first 10 items from the output:

```
# See a sample of the result
df_cosmos.head(10)
```

	Action	ItemRevenue	Country	Item
0	Viewed	9.00	Tunisia	Black Tee
1	Viewed	19.99	Antigua and Barbuda	Flannel Shirt
2	Added	3.75	Guinea-Bissau	Socks
3	Viewed	3.75	Guinea-Bissau	Socks
4	Viewed	55.00	Czech Republic	Rainjacket
5	Viewed	350.00	Iceland	Cosmos T-shirt
6	Added	19.99	Syrian Arab Republic	Button-Up Shirt
7	Viewed	19.99	Syrian Arab Republic	Button-Up Shirt
8	Viewed	33.00	Tuvalu	Red Top
9	Viewed	14.00	Cape Verde	Flip Flop Shoes

Run queries and analyze your data

In this section, you will run some queries on the data retrieved.

- **Query1**: Run a Group by query on the DataFrame to get the sum of total sales revenue for each country/region and display 5 items from the results. In a new notebook cell, run the following code:

  ```
  df_revenue = df_cosmos.groupby("Country").sum().reset_index()
  display(df_revenue.head(5))
  ```

	Country	ItemRevenue
0	Afghanistan	785.44
1	Albania	605.80
2	Algeria	1058.98
3	American Samoa	229.00
4	Andorra	247.49

- **Query2**: To get a list of top five purchased items, open a new notebook cell and run the following code:

  ```
  import pandas as pd

  ## What are the top 5 purchased items?
  pd.DataFrame(df_cosmos[df_cosmos['Action']=='Purchased'].groupby('Item').size().sort_values(ascending=Fa
  lse).head(5), columns=['Count'])
  ```

[21]:

Item	Count
Puffy Jacket	25
Athletic Shoes	20
Athletic Shorts	19
Crewneck Sweater	14
Light Jeans	13

Visualize your data

1. Now that we have our data on revenue from the Azure Cosmos container, you can visualize your data with a visualization library of your choice. In this tutorial, we will use Bokeh library. Open a new notebook cell and run the following code to install the Bokeh library. After all the requirements are satisfied, the library will be installed.

```
import sys
!{sys.executable} -m pip install bokeh --user
```

2. Next prepare to plot the data on a map. Join the data in Azure Cosmos DB with country/region information located in Azure Blob storage and convert the result to GeoJSON format. Copy the following code to a new notebook cell and run it.

```
import urllib.request, json
import geopandas as gpd

# Load country/region information for mapping
countries =
gpd.read_file("https://cosmosnotebooksdata.blob.core.windows.net/notebookdata/countries.json")

# Merge the countries/regions dataframe with our data in Azure Cosmos DB, joining on country/region code
df_merged = countries.merge(df_revenue, left_on = 'admin', right_on = 'Country', how='left')

# Convert to GeoJSON so bokeh can plot it
merged_json = json.loads(df_merged.to_json())
json_data = json.dumps(merged_json)
```

3. Visualize the sales revenue of different countries/regions on a world map by running the following code in a new notebook cell:

```
from bokeh.io import output_notebook, show
from bokeh.plotting import figure
from bokeh.models import GeoJSONDataSource, LinearColorMapper, ColorBar
from bokeh.palettes import brewer

#Input GeoJSON source that contains features for plotting.
geosource = GeoJSONDataSource(geojson = json_data)

#Choose our choropleth color palette: https://bokeh.pydata.org/en/latest/docs/reference/palettes.html
palette = brewer['YlGn'][8]

#Reverse color order so that dark green is highest revenue
palette = palette[::-1]

#Instantiate LinearColorMapper that linearly maps numbers in a range, into a sequence of colors.
color_mapper = LinearColorMapper(palette = palette, low = 0, high = 1000)

#Define custom tick labels for color bar.
tick_labels = {'0': '$0', '250': '$250', '500':'$500', '750':'$750', '1000':'$1000', '1250':'$1250',
'1500':'$1500','1750':'$1750', '2000': '>$2000'}

#Create color bar.
color_bar = ColorBar(color_mapper=color_mapper, label_standoff=8,width = 500, height = 20,
border_line_color=None,location = (0,0), orientation = 'horizontal', major_label_overrides =
tick_labels)

#Create figure object.
p = figure(title = 'Sales revenue by country', plot_height = 600 , plot_width = 1150, toolbar_location =
None)
p.xgrid.grid_line_color = None
p.ygrid.grid_line_color = None

#Add patch renderer to figure.
p.patches('xs','ys', source = geosource,fill_color = {'field' :'ItemRevenue', 'transform' :
color_mapper},
           line_color = 'black', line_width = 0.25, fill_alpha = 1)

#Specify figure layout.
p.add_layout(color_bar, 'below')

#Display figure inline in Jupyter Notebook.
output_notebook()

#Display figure.
show(p)
```

The output displays the world map with different colors. The colors darker to lighter represent the countries/regions with highest revenue to lowest revenue.

4. Let's see another case of data visualization. The WebsiteData container has record of users who viewed an item, added to their cart, and purchased the item. Let's plot the conversion rate of items purchased. Run the following code in a new cell to visualize the conversion rate for each item:

```
from bokeh.io import show, output_notebook
from bokeh.plotting import figure
from bokeh.palettes import Spectral3
from bokeh.transform import factor_cmap
from bokeh.models import ColumnDataSource, FactorRange

# Get the top 10 items as an array
top_10_items =
df_cosmos[df_cosmos['Action']=='Purchased'].groupby('Item').size().sort_values(ascending=False)
[:10].index.values.tolist()

# Filter our data to only these 10 items
df_top10 = df_cosmos[df_cosmos['Item'].isin(top_10_items)]

# Group by Item and Action, sorting by event count
df_top10_sorted = df_top10.groupby(['Item', 'Action']).count().rename(columns={'Country':'ResultCount'},
inplace=False).reset_index().sort_values(['Item', 'ResultCount'], ascending = False).set_index(['Item',
'Action'])

# Get sorted X-axis values - this way, we can display the funnel of view -> add -> purchase
x_axis_values = df_top10_sorted.index.values.tolist()

group = df_top10_sorted.groupby(['Item', 'Action'])

# Specifiy colors for X axis
index_cmap = factor_cmap('Item_Action', palette=Spectral3, factors=sorted(df_top10.Action.unique()),
start=1, end=2)

# Create the plot

p = figure(plot_width=1200, plot_height=500, title="Conversion rate of items from View -> Add to cart ->
Purchase", x_range=FactorRange(*x_axis_values), toolbar_location=None, tooltips=[("Number of events",
"@ResultCount_max"), ("Item, Action", "@Item_Action")])

p.vbar(x='Item_Action', top='ItemRevenue_max', width=1, source=group,
        line_color="white", fill_color=index_cmap, )

#Configure how the plot looks
p.y_range.start = 0
p.x_range.range_padding = 0.05
p.xgrid.grid_line_color = None
p.xaxis.major_label_orientation = 1.2
p.outline_line_color = "black"
p.xaxis.axis_label = "Item"
p.yaxis.axis_label = "Count"

#Display figure inline in Jupyter Notebook.
output_notebook()

#Display figure.
show(p)
```

Next steps

Tutorial: Set up Azure Cosmos DB global distribution using the SQL API

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

In this article, we show how to use the Azure portal to set up Azure Cosmos DB global distribution and then connect using the SQL API.

This article covers the following tasks:

- Configure global distribution using the Azure portal
- Configure global distribution using the SQL APIs

Add global database regions using the Azure portal

Azure Cosmos DB is available in all Azure regions worldwide. After selecting the default consistency level for your database account, you can associate one or more regions (depending on your choice of default consistency level and global distribution needs).

1. In the Azure portal, in the left bar, click **Azure Cosmos DB**.
2. In the **Azure Cosmos DB** page, select the database account to modify.
3. In the account page, click **Replicate data globally** from the menu.
4. In the **Replicate data globally** page, select the regions to add or remove by clicking regions in the map, and then click **Save**. There is a cost to adding regions, see the pricing page or the Distribute data globally with Azure Cosmos DB article for more information.

Once you add a second region, the **Manual Failover** option is enabled on the **Replicate data globally** page in the portal. You can use this option to test the failover process or change the primary write region. Once you add a third region, the **Failover Priorities** option is enabled on the same page so that you can change the failover order for reads.

Selecting global database regions

There are two common scenarios for configuring two or more regions:

1. Delivering low-latency access to data to end users no matter where they are located around the globe
2. Adding regional resiliency for business continuity and disaster recovery (BCDR)

For delivering low-latency to end users, it is recommended that you deploy both the application and Azure Cosmos DB in the regions that correspond to where the application's users are located.

For BCDR, it is recommended to add regions based on the region pairs described in the Business continuity and disaster recovery (BCDR): Azure Paired Regions article.

Connecting to a preferred region using the SQL API

In order to take advantage of global distribution, client applications can specify the ordered preference list of regions to be used to perform document operations. Based on the Azure Cosmos DB account configuration, current regional availability and the preference list specified, the most optimal endpoint will be chosen by the SQL SDK to perform write and read operations.

This preference list is specified when initializing a connection using the SQL SDKs. The SDKs accept an optional parameter `PreferredLocations` that is an ordered list of Azure regions.

The SDK will automatically send all writes to the current write region. All reads will be sent to the first available region in the preferred locations list. If the request fails, the client will fail down the list to the next region.

The SDK will only attempt to read from the regions specified in preferred locations. So, for example, if the Azure Cosmos account is available in four regions, but the client only specifies two read(non-write) regions within the `PreferredLocations`, then no reads will be served out of the read region that is not specified in `PreferredLocations`. If the read regions specified in the `PreferredLocations` list are not available, reads will be served out of write region.

The application can verify the current write endpoint and read endpoint chosen by the SDK by checking two properties, `WriteEndpoint` and `ReadEndpoint`, available in SDK version 1.8 and above. If the `PreferredLocations` property is not set, all requests will be served from the current write region.

If you don't specify the preferred locations but used the `setCurrentLocation` method, the SDK automatically populates the preferred locations based on the current region that the client is running in. The SDK orders the regions based on the proximity of a region to the current region.

.NET SDK

The SDK can be used without any code changes. In this case, the SDK automatically directs both reads and writes to the current write region.

In version 1.8 and later of the .NET SDK, the ConnectionPolicy parameter for the DocumentClient constructor has a property called Microsoft.Azure.Documents.ConnectionPolicy.PreferredLocations. This property is of type Collection `<string>` and should contain a list of region names. The string values are formatted per the region name column on the Azure Regions page, with no spaces before or after the first and last character respectively.

The current write and read endpoints are available in DocumentClient.WriteEndpoint and DocumentClient.ReadEndpoint respectively.

> **NOTE**
> The URLs for the endpoints should not be considered as long-lived constants. The service may update these at any point. The SDK handles this change automatically.

- .NET SDK V2
- .NET SDK V3

If you are using the .NET V2 SDK, use the `PreferredLocations` property to set the preferred region.

```
// Getting endpoints from application settings or other configuration location
Uri accountEndPoint = new Uri(Properties.Settings.Default.GlobalDatabaseUri);
string accountKey = Properties.Settings.Default.GlobalDatabaseKey;

ConnectionPolicy connectionPolicy = new ConnectionPolicy();

//Setting read region selection preference
connectionPolicy.PreferredLocations.Add(LocationNames.WestUS); // first preference
connectionPolicy.PreferredLocations.Add(LocationNames.EastUS); // second preference
connectionPolicy.PreferredLocations.Add(LocationNames.NorthEurope); // third preference

// initialize connection
DocumentClient docClient = new DocumentClient(
    accountEndPoint,
    accountKey,
    connectionPolicy);

// connect to DocDB
await docClient.OpenAsync().ConfigureAwait(false);
```

Alternatively, you can use the `SetCurrentLocation` property and let the SDK choose the preferred location based on proximity.

```
// Getting endpoints from application settings or other configuration location
Uri accountEndPoint = new Uri(Properties.Settings.Default.GlobalDatabaseUri);
string accountKey = Properties.Settings.Default.GlobalDatabaseKey;

ConnectionPolicy connectionPolicy = new ConnectionPolicy();

connectionPolicy.SetCurrentLocation("West US 2"); /

// initialize connection
DocumentClient docClient = new DocumentClient(
    accountEndPoint,
    accountKey,
    connectionPolicy);

// connect to DocDB
await docClient.OpenAsync().ConfigureAwait(false);
```

Node.js/JavaScript

> **NOTE**
>
> The URLs for the endpoints should not be considered as long-lived constants. The service may update these at any point. The SDK will handle this change automatically.

Below is a code example for Node.js/Javascript.

```
// Setting read region selection preference, in the following order -
// 1 - West US
// 2 - East US
// 3 - North Europe
const preferredLocations = ['West US', 'East US', 'North Europe'];

// initialize the connection
const client = new CosmosClient{ endpoint, key, connectionPolicy: { preferredLocations } });
```

Python SDK

The following code shows how to set preferred locations by using the Python SDK:

```
connectionPolicy = documents.ConnectionPolicy()
connectionPolicy.PreferredLocations = ['West US', 'East US', 'North Europe']
client = cosmos_client.CosmosClient(ENDPOINT, {'masterKey': MASTER_KEY}, connectionPolicy)
```

Java V4 SDK

The following code shows how to set preferred locations by using the Java SDK:

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
ArrayList<String> preferredRegions = new ArrayList<String>();
preferredRegions.add("East US");
preferredRegions.add( "West US");
preferredRegions.add("Canada Central");

CosmosAsyncClient client =
        new CosmosClientBuilder()
                .endpoint(HOST)
                .key(MASTER_KEY)
                .preferredRegions(preferredRegions)
                .contentResponseOnWriteEnabled(true)
                .buildAsyncClient();
```

REST

Once a database account has been made available in multiple regions, clients can query its availability by performing a GET request on this URI `https://{databaseaccount}.documents.azure.com/`

The service will return a list of regions and their corresponding Azure Cosmos DB endpoint URIs for the replicas. The current write region will be indicated in the response. The client can then select the appropriate endpoint for all further REST API requests as follows.

Example response

```
{
    "_dbs": "//dbs/",
    "media": "//media/",
    "writableLocations": [
        {
            "Name": "West US",
            "DatabaseAccountEndpoint": "https://globaldbexample-westus.documents.azure.com:443/"
        }
    ],
    "readableLocations": [
        {
            "Name": "East US",
            "DatabaseAccountEndpoint": "https://globaldbexample-eastus.documents.azure.com:443/"
        }
    ],
    "MaxMediaStorageUsageInMB": 2048,
    "MediaStorageUsageInMB": 0,
    "ConsistencyPolicy": {
        "defaultConsistencyLevel": "Session",
        "maxStalenessPrefix": 100,
        "maxIntervalInSeconds": 5
    },
    "addresses": "//addresses/",
    "id": "globaldbexample",
    "_rid": "globaldbexample.documents.azure.com",
    "_self": "",
    "_ts": 0,
    "_etag": null
}
```

- All PUT, POST and DELETE requests must go to the indicated write URI
- All GETs and other read-only requests (for example queries) may go to any endpoint of the client's choice

Write requests to read-only regions will fail with HTTP error code 403 ("Forbidden").

If the write region changes after the client's initial discovery phase, subsequent writes to the previous write region will fail with HTTP error code 403 ("Forbidden"). The client should then GET the list of regions again to get the updated write region.

That's it, that completes this tutorial. You can learn how to manage the consistency of your globally replicated account by reading Consistency levels in Azure Cosmos DB. And for more information about how global database replication works in Azure Cosmos DB, see Distribute data globally with Azure Cosmos DB.

Next steps

In this tutorial, you've done the following:

- Configure global distribution using the Azure portal
- Configure global distribution using the SQL APIs

You can now proceed to the next tutorial to learn how to develop locally using the Azure Cosmos DB local emulator.

Develop locally with the emulator

Azure Cosmos DB: .NET examples for the SQL API

11/2/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

The azure-cosmos-dotnet-v2 GitHub repository includes the latest .NET sample solutions to perform CRUD and other common operations on Azure Cosmos DB resources. This article provides:

- Links to the tasks in each of the example C# project files.
- Links to the related API reference content.

For .NET SDK Version 3.0 (Preview) code samples, see the latest samples in the azure-cosmos-dotnet-v3 GitHub repository.

Prerequisites

Visual Studio 2019 with the Azure development workflow installed

- You can download and use the **free** Visual Studio 2019 Community Edition. Make sure that you enable **Azure development** during the Visual Studio setup.

The Microsoft.Azure.DocumentDB NuGet package

An Azure subscription or free Cosmos DB trial account

- If you don't have an Azure subscription, create a free account before you begin.
- You can activate Visual Studio subscriber benefits: Your Visual Studio subscription gives you credits every month, which you can use for paid Azure services.
- You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

> **NOTE**
> The samples are self-contained, and set up and clean up after themselves with multiple calls to CreateDocumentCollectionAsync(). Each occurrence bills your subscription for one hour of usage in your collection's performance tier.

Database examples

The RunDatabaseDemo method of the sample *DatabaseManagement* project shows how to do the following tasks. To learn about Azure Cosmos databases before you run the following samples, see Work with databases, containers, and items.

TASK	API REFERENCE
Create a database	DocumentClient.CreateDatabaseIfNotExistsAsync
Read a database by ID	DocumentClient.ReadDatabaseAsync

TASK	API REFERENCE
Read all the databases	DocumentClient.ReadDatabaseFeedAsync
Delete a database	DocumentClient.DeleteDatabaseAsync

Collection examples

The RunCollectionDemo method of the sample *CollectionManagement* project shows how to do the following tasks. To learn about Azure Cosmos collections before you run the following samples, see Work with databases, containers, and items.

TASK	API REFERENCE
Create a collection	DocumentClient.CreateDocumentCollectionIfNotExistsAsync
Change configured performance of a collection	DocumentClient.ReplaceOfferAsync
Get a collection by ID	DocumentClient.ReadDocumentCollectionAsync
Read all the collections in a database	DocumentClient.ReadDocumentCollectionFeedAsync
Delete a collection	DocumentClient.DeleteDocumentCollectionAsync

Document examples

The RunDocumentsDemo method of the sample *DocumentManagement* project shows how to do the following tasks. To learn about Azure Cosmos documents before you run the following samples, see Work with databases, containers, and items.

TASK	API REFERENCE
Create a document	DocumentClient.CreateDocumentAsync
Read a document by ID	DocumentClient.ReadDocumentAsync
Read all the documents in a collection	DocumentClient.ReadDocumentFeedAsync
Query for documents	DocumentClient.CreateDocumentQuery
Replace a document	DocumentClient.ReplaceDocumentAsync
Upsert a document	DocumentClient.UpsertDocumentAsync
Delete a document	DocumentClient.DeleteDocumentAsync
Working with .NET dynamic objects	DocumentClient.CreateDocumentAsync DocumentClient.ReadDocumentAsync DocumentClient.ReplaceDocumentAsync
Replace document with conditional ETag check	DocumentClient.AccessCondition Documents.Client.AccessConditionType

TASK	API REFERENCE
Read document only if document has changed	DocumentClient.AccessCondition Documents.Client.AccessConditionType

Indexing examples

The RunIndexDemo method of the sample *IndexManagement* project shows how to do the following tasks. To learn about indexing in Azure Cosmos DB before you run the following samples, see index policies, index types, and index paths.

TASK	API REFERENCE
Exclude a document from the index	IndexingDirective.Exclude
Use Lazy indexing	IndexingPolicy.IndexingMode
Exclude specified document paths from the index	IndexingPolicy.ExcludedPaths
Force a range scan operation on a hash indexed path	FeedOptions.EnableScanInQuery
Use range indexes on strings	IndexingPolicy.IncludedPaths RangeIndex
Perform an index transform	ReplaceDocumentCollectionAsync

Geospatial examples

The RunDemoAsync method of the sample *Geospatial* project shows how to do the following tasks. To learn about GeoJSON and geospatial data before you run the following samples, see Use geospatial and GeoJSON location data.

TASK	API REFERENCE
Enable geospatial indexing on a new collection	IndexingPolicy IndexKind.Spatial DataType.Point
Insert documents with GeoJSON points	DocumentClient.CreateDocumentAsync DataType.Point
Find points within a specified distance	ST_DISTANCE GeometryOperationExtensions.Distance
Find points within a polygon	ST_WITHIN GeometryOperationExtensions.Within Polygon
Enable geospatial indexing on an existing collection	DocumentClient.ReplaceDocumentCollectionAsync DocumentCollection.IndexingPolicy

TASK	API REFERENCE
Validate point and polygon data	ST_ISVALID ST_ISVALIDDETAILED GeometryOperationExtensions.IsValid GeometryOperationExtensions.IsValidDetailed

Query examples

The RunDemoAsync method of the sample *Queries* project shows how to do the following tasks using the SQL query grammar, the LINQ provider with query, and Lambda. To learn about the SQL query reference in Azure Cosmos DB before you run the following samples, see SQL query examples for Azure Cosmos DB.

TASK	API REFERENCE
Query for all documents	DocumentQueryable.CreateDocumentQuery
Query for equality using ==	DocumentQueryable.CreateDocumentQuery
Query for inequality using != and NOT	DocumentQueryable.CreateDocumentQuery
Query using range operators like >, <, >=, <=	DocumentQueryable.CreateDocumentQuery
Query using range operators against strings	DocumentQueryable.CreateDocumentQuery
Query with ORDER BY	DocumentQueryable.CreateDocumentQuery
Query with aggregate functions	DocumentQueryable.CreateDocumentQuery
Work with subdocuments	DocumentQueryable.CreateDocumentQuery
Query with intra-document Joins	DocumentQueryable.CreateDocumentQuery
Query with string, math, and array operators	DocumentQueryable.CreateDocumentQuery
Query with parameterized SQL using SqlQuerySpec	DocumentQueryable.CreateDocumentQuery SqlQuerySpec
Query with explicit paging	DocumentQueryable.CreateDocumentQuery
Query partitioned collections in parallel	DocumentQueryable.CreateDocumentQuery
Query with ORDER BY for partitioned collections	DocumentQueryable.CreateDocumentQuery

Change feed examples

The RunDemoAsync method of the sample *ChangeFeed* project shows how to do the following tasks. To learn about change feed in Azure Cosmos DB before you run the following samples, see Read Azure Cosmos DB change feed and Change feed processor.

TASK	API REFERENCE
Read change feed	DocumentClient.CreateDocumentChangeFeedQuery
Read partition key ranges	DocumentClient.ReadPartitionKeyRangeFeedAsync

The change feed processor sample, ChangeFeedMigrationTool, shows how to use the change feed processor library to replicate data to another Cosmos container.

Server-side programming examples

The RunDemoAsync method of the sample *ServerSideScripts* project shows how to do the following tasks. To learn about server-side programming in Azure Cosmos DB before you run the following samples, see Stored procedures, triggers, and user-defined functions.

TASK	API REFERENCE
Create a stored procedure	DocumentClient.CreateStoredProcedureAsync
Execute a stored procedure	DocumentClient.ExecuteStoredProcedureAsync
Read a document feed for a stored procedure	DocumentClient.ReadDocumentFeedAsync
Create a stored procedure with ORDER BY	DocumentClient.CreateStoredProcedureAsync
Create a pre-trigger	DocumentClient.CreateTriggerAsync
Create a post-trigger	DocumentClient.CreateTriggerAsync
Create a user-defined function (UDF)	DocumentClient.CreateUserDefinedFunctionAsync

User management examples

The RunDemoAsync method of the sample *UserManagement* project shows how to do the following tasks:

TASK	API REFERENCE
Create a user	DocumentClient.CreateUserAsync
Set permissions on a collection or document	DocumentClient.CreatePermissionAsync
Get a list of a user's permissions	DocumentClient.ReadUserAsync DocumentClient.ReadPermissionFeedAsync

Azure Cosmos DB.NET V3 SDK (Microsoft.Azure.Cosmos) examples for the SQL API

11/2/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

The azure-cosmos-dotnet-v3 GitHub repository includes the latest .NET sample solutions to perform CRUD and other common operations on Azure Cosmos DB resources. If you're familiar with the previous version of the .NET SDK, you may be used to the terms collection and document. Because Azure Cosmos DB supports multiple API models, version 3.0 of the .NET SDK uses the generic terms "container" and "item". A container can be a collection, graph, or table. An item can be a document, edge/vertex, or row, and is the content inside a container. This article provides:

- Links to the tasks in each of the example C# project files.
- Links to the related API reference content.

Prerequisites

Visual Studio 2019 with the Azure development workflow installed

- You can download and use the **free** Visual Studio 2019 Community Edition. Make sure that you enable **Azure development** during the Visual Studio setup.

  The Microsoft.Azure.cosmos NuGet package

An Azure subscription or free Cosmos DB trial account

- If you don't have an Azure subscription, create a free account before you begin.
- You can activate Visual Studio subscriber benefits: Your Visual Studio subscription gives you credits every month, which you can use for paid Azure services.
- You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

> **NOTE**
>
> The samples are self-contained, and set up and clean up after themselves. Each occurrence bills your subscription for one hour of usage in your container's performance tier.

Database examples

The RunDatabaseDemo method of the sample *DatabaseManagement* project shows how to do the following tasks. To learn about Azure Cosmos databases before you run the following samples, see Work with databases, containers, and items.

TASK	API REFERENCE
Create a database	CosmosClient.CreateDatabaseIfNotExistsAsync
Read a database by ID	Database.ReadAsync
Read all the databases for an account	CosmosClient.GetDatabaseQueryIterator
Delete a database	Database.DeleteAsync

Container examples

The RunContainerDemo method of the sample *ContainerManagement* project shows how to do the following tasks. To learn about Azure Cosmos containers before you run the following samples, see Work with databases, containers, and items.

TASK	API REFERENCE
Create a container	Database.CreateContainerIfNotExistsAsync
Create a container with custom index policy	Database.CreateContainerIfNotExistsAsync
Change configured performance of a container	Container.ReplaceThroughputAsync
Get a container by ID	Container.ReadContainerAsync
Read all the containers in a database	Database.GetContainerQueryIterator
Delete a container	Container.DeleteContainerAsync

Item examples

The RunItemsDemo method of the sample *ItemManagement* project shows how to do the following tasks. To learn about Azure Cosmos items before you run the following samples, see Work with databases, containers, and items.

TASK	API REFERENCE
Create an item	Container.CreateItemAsync
Read an item by ID	container.ReadItemAsync
Query for items	container.GetItemQueryIterator
Replace an item	container.ReplaceItemAsync
Upsert an item	container.UpsertItemAsync
Delete an item	container.DeleteItemAsync
Replace an item with conditional ETag check	RequestOptions.IfMatchEtag

Indexing examples

The RunIndexDemo method of the sample *IndexManagement* project shows how to do the following tasks. To learn about indexing in Azure Cosmos DB before you run the following samples, see index policies, index types, and index paths.

TASK	API REFERENCE
Exclude an item from the index	IndexingDirective.Exclude
Use Lazy indexing	IndexingPolicy.IndexingMode
Exclude specified item paths from the index	IndexingPolicy.ExcludedPaths

Query examples

The RunDemoAsync method of the sample *Queries* project shows how to do the following tasks using the SQL query grammar, the LINQ provider with query, and Lambda. To learn about the SQL query reference in Azure Cosmos DB before you run the following samples, see SQL query examples for Azure Cosmos DB.

TASK	API REFERENCE
Query items from single partition	container.GetItemQueryIterator
Query items from multiple partitions	container.GetItemQueryIterator
Query using a SQL statement	container.GetItemQueryIterator

Change feed examples

The RunBasicChangeFeed method of the sample *ChangeFeed* project shows how to do the following tasks. To learn about change feed in Azure Cosmos DB before you run the following samples, see Read Azure Cosmos DB change feed and Change feed processor.

TASK	API REFERENCE
Basic change feed functionality	Container.GetChangeFeedProcessorBuilder
Read change feed from a specific time	Container.GetChangeFeedProcessorBuilder
Read change feed from the beginning	ChangeFeedProcessorBuilder.WithStartTime(DateTime)
MIgrate from change feed processor to change feed in V3 SDK	Container.GetChangeFeedProcessorBuilder

Server-side programming examples

The RunDemoAsync method of the sample *ServerSideScripts* project shows how to do the following tasks. To learn about server-side programming in Azure Cosmos DB before you run the following samples, see Stored procedures, triggers, and user-defined functions.

TASK	API REFERENCE
Create a stored procedure	Scripts.CreateStoredProcedureAsync
Execute a stored procedure	Scripts.ExecuteStoredProcedureAsync
Delete a stored procedure	Scripts.DeleteStoredProcedureAsync

Azure Cosmos DB SQL API: Java SDK v4 examples

12/4/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> To learn more about Java SDK v4, please see the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, Azure Cosmos DB Java SDK v4 performance tips, and Azure Cosmos DB Java SDK v4 troubleshooting guide for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

> **IMPORTANT**
>
> If you don't have an Azure subscription, create a free account before you begin.
>
> - You can activate Visual Studio subscriber benefits: Your Visual Studio subscription gives you credits every month that you can use for paid Azure services.
>
> You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

The latest sample applications that perform CRUD operations and other common operations on Azure Cosmos DB resources are included in the azure-cosmos-java-sql-api-samples GitHub repository. This article provides:

- Links to the tasks in each of the example Java project files.
- Links to the related API reference content.

Prerequisites

You need the following to run this sample application:

- Java Development Kit 8
- Azure Cosmos DB Java SDK v4

You can optionally use Maven to get the latest Azure Cosmos DB Java SDK v4 binaries for use in your project. Maven automatically adds any necessary dependencies. Otherwise, you can directly download the dependencies listed in the pom.xml file and add them to your build path.

```
<dependency>
 <groupId>com.azure</groupId>
 <artifactId>azure-cosmos</artifactId>
 <version>LATEST</version>
</dependency>
```

Running the sample applications

Clone the sample repo:

```
$ git clone https://github.com/Azure-Samples/azure-cosmos-java-sql-api-samples.git

$ cd azure-cosmos-java-sql-api-samples
```

You can run the samples using either an IDE (Eclipse, IntelliJ, or VSCODE) or from the command line using Maven.

These environment variables must be set

```
ACCOUNT_HOST=your account hostname;ACCOUNT_KEY=your account primary key
```

in order to give the samples read/write access to your account.

To run a sample, specify its Main Class

```
com.azure.cosmos.examples.sample.synchronicity.MainClass
```

where *sample.synchronicity.MainClass* can be

- crudquickstart.sync.SampleCRUDQuickstart
- crudquickstart.async.SampleCRUDQuickstartAsync
- indexmanagement.sync.SampleIndexManagement
- indexmanagement.async.SampleIndexManagementAsync
- storedprocedure.sync.SampleStoredProcedure
- storedprocedure.async.SampleStoredProcedureAsync
- changefeed.SampleChangeFeedProcessor *(Changefeed has only an async sample, no sync sample.)* ...etc...

> **NOTE**
> Each sample is self-contained; it sets itself up and cleans up after itself. The samples issue multiple calls to create a `CosmosContainer`. Each time this is done, your subscription is billed for 1 hour of usage for the performance tier of the collection created.

Database examples

The Database CRUD Samples file shows how to perform the following tasks. To learn about the Azure Cosmos databases before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a database	CosmosClient.createDatabaseIfNotExists
Read a database by ID	CosmosClient.getDatabase
Read all the databases	CosmosClient.readAllDatabases
Delete a database	CosmosDatabase.delete

Collection examples

The Collection CRUD Samples file shows how to perform the following tasks. To learn about the Azure Cosmos

collections before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a collection	CosmosDatabase.createContainerIfNotExists
Change configured performance of a collection	CosmosContainer.replaceProvisionedThroughput
Get a collection by ID	CosmosDatabase.getContainer
Read all the collections in a database	CosmosDatabase.readAllContainers
Delete a collection	CosmosContainer.delete

Autoscale collection examples

To learn more about autoscale before running these samples, take a look at these instructions for enabling autoscale in your account and in your databases and containers.

The autoscale Database CRUD Samples file shows how to perform the following tasks.

TASK	API REFERENCE
Create a database with specified autoscale max throughput	CosmosClient.createDatabase ThroughputProperties.createAutoscaledThroughput

The autoscale Collection CRUD Samples file shows how to perform the following tasks.

TASK	API REFERENCE
Create a collection with specified autoscale max throughput	CosmosDatabase.createContainerIfNotExists
Change configured autoscale max throughput of a collection	CosmosContainer.replaceThroughput
Read autoscale throughput configuration of a collection	CosmosContainer.readThroughput

Analytical storage collection examples

The Analytical storage Collection CRUD Samples file shows how to perform the following tasks. To learn about the Azure Cosmos collections before running the following samples, read about Azure Cosmos DB Synapse and Analytical Store.

TASK	API REFERENCE
Create a collection	CosmosDatabase.createContainerIfNotExists

Document examples

The Document CRUD Samples file shows how to perform the following tasks. To learn about the Azure Cosmos documents before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a document	CosmosContainer.createItem
Read a document by ID	CosmosContainer.readItem
Query for documents	CosmosContainer.queryItems
Replace a document	CosmosContainer.replaceItem
Upsert a document	CosmosContainer.upsertItem
Delete a document	CosmosContainer.deleteItem
Replace a document with conditional ETag check	AccessCondition.setType AccessCondition.setCondition
Read document only if document has changed	AccessCondition.setType AccessCondition.setCondition

Indexing examples

The Collection CRUD Samples file shows how to perform the following tasks. To learn about indexing in Azure Cosmos DB before running the following samples, see indexing policies, indexing types, and indexing paths conceptual articles.

TASK	API REFERENCE
Exclude a document from the index	ExcludedIndex IndexingPolicy
Use Lazy Indexing	IndexingPolicy.IndexingMode
Include specified documents paths in the index	IndexingPolicy.IncludedPaths
Exclude specified documents paths from the index	IndexingPolicy.ExcludedPaths
Create a composite index	IndexingPolicy.setCompositeIndexes CompositePath
Force a range scan operation on a hash indexed path	FeedOptions.EnableScanInQuery
Use range indexes on Strings	IndexingPolicy.IncludedPaths RangeIndex
Perform an index transform	-
Create a geospatial index	IndexingPolicy.setSpatialIndexes SpatialSpec SpatialType

For more information about indexing, see Azure Cosmos DB indexing policies.

Query examples

The Query Samples file shows how to do the following tasks using the SQL query grammar. To learn about the SQL query reference in Azure Cosmos DB before you run the following samples, see SQL query examples for Azure Cosmos DB.

TASK	API REFERENCE
Query for all documents	CosmosContainer.queryItems
Query for equality using ==	CosmosContainer.queryItems
Query for inequality using != and NOT	CosmosContainer.queryItems
Query using range operators like >, <, >=, <=	CosmosContainer.queryItems
Query using range operators against strings	CosmosContainer.queryItems
Query with ORDER BY	CosmosContainer.queryItems
Query with DISTINCT	CosmosContainer.queryItems
Query with aggregate functions	CosmosContainer.queryItems
Work with subdocuments	CosmosContainer.queryItems
Query with intra-document Joins	CosmosContainer.queryItems
Query with string, math, and array operators	CosmosContainer.queryItems
Query with parameterized SQL using SqlQuerySpec	CosmosContainer.queryItems
Query with explicit paging	CosmosContainer.queryItems
Query partitioned collections in parallel	CosmosContainer.queryItems
Query with ORDER BY for partitioned collections	CosmosContainer.queryItems

Change feed examples

The Change Feed Processor Sample file shows how to do the following tasks. To learn about change feed in Azure Cosmos DB before you run the following samples, see Read Azure Cosmos DB change feed and Change feed processor.

TASK	API REFERENCE
Basic change feed functionality	ChangeFeedProcessor.changeFeedProcessorBuilder
Read change feed from a specific time	ChangeFeedProcessor.changeFeedProcessorBuilder
Read change feed from the beginning	-

Server-side programming examples

The Stored Procedure Sample file shows how to do the following tasks. To learn about server-side programming in Azure Cosmos DB before you run the following samples, see Stored procedures, triggers, and user-defined functions.

TASK	API REFERENCE
Create a stored procedure	CosmosScripts.createStoredProcedure
Execute a stored procedure	CosmosStoredProcedure.execute
Delete a stored procedure	CosmosStoredProcedure.delete

User management examples

The User Management Sample file shows how to do the following tasks:

TASK	API REFERENCE
Create a user	-
Set permissions on a collection or document	-
Get a list of a user's permissions	-

Azure Cosmos DB SQL API: Spring Data Azure Cosmos DB v3 examples

11/2/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> These release notes are for version 3 of Spring Data Azure Cosmos DB. You can find release notes for version 2 here.
>
> Spring Data Azure Cosmos DB supports only the SQL API.
>
> See these articles for information about Spring Data on other Azure Cosmos DB APIs:
>
> - Spring Data for Apache Cassandra with Azure Cosmos DB
> - Spring Data MongoDB with Azure Cosmos DB
> - Spring Data Gremlin with Azure Cosmos DB

> **IMPORTANT**
>
> If you don't have an Azure subscription, create a free account before you begin.
>
> - You can activate Visual Studio subscriber benefits: Your Visual Studio subscription gives you credits every month that you can use for paid Azure services.
>
> You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

The latest sample applications that perform CRUD operations and other common operations on Azure Cosmos DB resources are included in the azure-spring-data-cosmos-java-sql-api-samples GitHub repository. This article provides:

- Links to the tasks in each of the example Spring Data Azure Cosmos DB project files.
- Links to the related API reference content.

Prerequisites

You need the following to run this sample application:

- Java Development Kit 8
- Spring Data Azure Cosmos DB v3

You can optionally use Maven to get the latest Spring Data Azure Cosmos DB v3 binaries for use in your project. Maven automatically adds any necessary dependencies. Otherwise, you can directly download the dependencies listed in the **pom.xml** file and add them to your build path.

```
<dependency>
 <groupId>com.azure</groupId>
 <artifactId>azure-spring-data-cosmos</artifactId>
 <version>LATEST</version>
</dependency>
```

Running the sample applications

Clone the sample repo:

```
$ git clone https://github.com/Azure-Samples/azure-spring-data-cosmos-java-sql-api-samples

$ cd azure-spring-data-cosmos-java-sql-api-samples
```

You can run the samples using either an IDE (Eclipse, IntelliJ, or VSCODE) or from the command line using Maven.

In **application.properties** these environment variables must be set

```
cosmos.uri=${ACCOUNT_HOST}
cosmos.key=${ACCOUNT_KEY}
cosmos.secondaryKey=${SECONDARY_ACCOUNT_KEY}

dynamic.collection.name=spel-property-collection
# Populate query metrics
cosmos.queryMetricsEnabled=true
```

in order to give the samples read/write access to your account, databases and containers.

Your IDE may provide the ability to execute the Spring Data sample code. Otherwise you may use the following terminal command to execute the sample:

```
mvn spring-boot:run
```

Document CRUD examples

The samples file shows how to perform the following tasks. To learn about Azure Cosmos documents before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a document	CosmosRepository.save
Read a document by ID	CosmosRepository.derivedQueryMethod
Delete all documents	CosmosRepository.deleteAll

Derived query method examples

The samples file shows how to perform the following tasks. To learn about Azure Cosmos DB queries before running the following samples, you may find it helpful to read Baeldung's Derived Query Methods in Spring article.

| Query for documents | CosmosRepository.derivedQueryMethod |

Custom query examples

The samples file shows how to do the following tasks using the SQL query grammar. To learn about the SQL query reference in Azure Cosmos DB before you run the following samples, see SQL query examples for Azure Cosmos DB.

TASK	API REFERENCE
Query for all documents	@Query annotation
Query for equality using ==	@Query annotation
Query for inequality using != and NOT	@Query annotation
Query using range operators like >, <, >=, <=	@Query annotation
Query using range operators against strings	@Query annotation
Query with ORDER BY	@Query annotation
Query with DISTINCT	@Query annotation
Query with aggregate functions	@Query annotation
Work with subdocuments	@Query annotation
Query with intra-document Joins	@Query annotation
Query with string, math, and array operators	@Query annotation

Node.js examples to manage data in Azure Cosmos DB

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Sample solutions that perform CRUD operations and other common operations on Azure Cosmos DB resources are included in the azure-cosmos-js GitHub repository. This article provides:

- Links to the tasks in each of the Node.js example project files.
- Links to the related API reference content.

Prerequisites

If you don't have an Azure subscription, create a free account before you begin.

- You can activate Visual Studio subscriber benefits: Your Visual Studio subscription gives you credits every month that you can use for paid Azure services.

You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments, or create an Azure Cosmos DB free tier account, with the first 400 RU/s and 5 GB of storage for free. You can also use the Azure Cosmos DB Emulator with a URI of `https://localhost:8081`. For the key to use with the emulator, see Authenticating requests.

You also need the JavaScript SDK.

> **NOTE**
> Each sample is self-contained, it sets itself up and cleans up after itself. As such, the samples issue multiple calls to Containers.create. Each time this is done your subscription will be billed for 1 hour of usage per the performance tier of the container being created.

Database examples

The DatabaseManagement file shows how to perform the CRUD operations on the database. To learn about the Azure Cosmos databases before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a database if it does not exist	Databases.createIfNotExists
List databases for an account	Databases.readAll
Read a database by ID	Database.read
Delete a database	Database.delete

Container examples

The ContainerManagement file shows how to perform the CRUD operations on the container. To learn about the Azure Cosmos collections before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a container if it does not exist	Containers.createIfNotExists
List containers for an account	Containers.readAll
Read a container definition	Container.read
Delete a container	Container.delete

Item examples

The ItemManagement file shows how to perform the CRUD operations on the item. To learn about the Azure Cosmos documents before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create items	Items.create
Read all items in a container	Items.readAll
Read an item by ID	Item.read
Read item only if item has changed	Item.read RequestOptions.accessCondition
Query for documents	Items.query
Replace an item	Item.replace
Replace item with conditional ETag check	Item.replace RequestOptions.accessCondition
Delete an item	Item.delete

Indexing examples

The IndexManagement file shows how to manage indexing. To learn about indexing in Azure Cosmos DB before running the following samples, see indexing policies, indexing types, and indexing paths conceptual articles.

TASK	API REFERENCE
Manually index a specific item	RequestOptions.indexingDirective: 'include'
Manually exclude a specific item from the index	RequestOptions.indexingDirective: 'exclude'
Exclude a path from the index	IndexingPolicy.ExcludedPath

TASK	API REFERENCE
Create a range index on a string path	IndexKind.Range, IndexingPolicy, Items.query
Create a container with default indexPolicy, then update this online	Containers.create

Server-side programming examples

The index.ts file of the ServerSideScripts project shows how to perform the following tasks. To learn about Server-side programming in Azure Cosmos DB before running the following samples, see Stored procedures, triggers, and user-defined functions conceptual article.

TASK	API REFERENCE
Create a stored procedure	StoredProcedures.create
Execute a stored procedure	StoredProcedure.execute

For more information about server-side programming, see Azure Cosmos DB server-side programming: Stored procedures, database triggers, and UDFs.

Azure Cosmos DB Python examples

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Sample solutions that do CRUD operations and other common operations on Azure Cosmos DB resources are included in the azure-documentdb-python GitHub repository. This article provides:

- Links to the tasks in each of the Python example project files.
- Links to the related API reference content.

Prerequisites

- A Cosmos DB Account. You options are:
  - Within an Azure active subscription:
    - Create an Azure free Account or use your existing subscription
    - Visual Studio Monthly Credits
    - Azure Cosmos DB Free Tier
  - Without an Azure active subscription:
    - Try Azure Cosmos DB for free, a tests environment that lasts for 30 days.
    - Azure Cosmos DB Emulator
- Python 2.7 or 3.5.3+, with the `python` executable in your `PATH`.
- Visual Studio Code.
- The Python extension for Visual Studio Code.
- Git.
- Azure Cosmos DB SQL API SDK for Python

Database examples

The database_management.py Python sample shows how to do the following tasks. To learn about the Azure Cosmos databases before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create a database	CosmosClient.create_database
Read a database by ID	CosmosClient.get_database_client
Query the databases	CosmosClient.query_databases
List databases for an account	CosmosClient.list_databases
Delete a database	CosmosClient.delete_database

Container examples

The container_management.py Python sample shows how to do the following tasks. To learn about the Azure

Cosmos collections before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Query for a container	database.query_containers
Create a container	database.create_container
List all the containers in a database	database.list_containers
Get a container by its ID	database.get_container_client
Manage container's provisioned throughput	container.read_offer, container.replace_throughput
Delete a container	database.delete_container

Item examples

The item_management.py Python sample shows how to do the following tasks. To learn about the Azure Cosmos documents before running the following samples, see Working with databases, containers, and items conceptual article.

TASK	API REFERENCE
Create items in a container	container.create_item
Read an item by its ID	container.read_item
Read all the items in a container	container.read_all_items
Query an item by its ID	container.query_items
Replace an item	container.replace_items
Upsert an item	container.upsert_item
Delete an item	container.delete_item
Get the change feed of items in a container	container.query_items_change_feed

Indexing examples

The index_management.py Python sample shows how to do the following tasks. To learn about indexing in Azure Cosmos DB before running the following samples, see indexing policies, indexing types, and indexing paths conceptual articles.

TASK	API REFERENCE
Exclude a specific item from indexing	documents.IndexingDirective.Exclude
Use manual indexing with specific items indexed	documents.IndexingDirective.Include

TASK	API REFERENCE
Exclude paths from indexing	Define paths to exclude in `IndexingPolicy` property
Use range indexes on strings	Define indexing policy with range indexes on string data type. `'kind': documents.IndexKind.Range`, `'dataType': documents.DataType.String`
Perform an index transformation	database.replace_container (use the updated indexing policy)
Use scans when only hash index exists on the path	set the `enable_scan_in_query=True` and `enable_cross_partition_query=True` when querying the items

Azure PowerShell samples for Azure Cosmos DB Core (SQL) API

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The following table includes links to commonly used Azure PowerShell scripts for Azure Cosmos DB. Use the links on the right to navigate to API specific samples. Common samples are the same across all APIs. Reference pages for all Azure Cosmos DB PowerShell cmdlets are available in the Azure PowerShell Reference. Please check for updates to `Az.CosmosDB` regularly. You can also fork these PowerShell samples for Cosmos DB from our GitHub repository, Cosmos DB PowerShell Samples on GitHub.

For PowerShell cmdlets for other APIs see PowerShell Samples for Cassandra, PowerShell Samples for MongoDB API, PowerShell Samples for Gremlin, PowerShell Samples for Table

Common Samples

TASK	DESCRIPTION
Update an account	Update a Cosmos DB account's default consistency level.
Update an account's regions	Update a Cosmos DB account's regions.
Change failover priority or trigger failover	Change the regional failover priority of an Azure Cosmos account or trigger a manual failover.
Account keys or connection strings	Get primary and secondary keys, connection strings or regenerate an account key of an Azure Cosmos DB account.
Create a Cosmos Account with IP Firewall	Create an Azure Cosmos DB account with IP Firewall enabled.

Core (SQL) API Samples

TASK	DESCRIPTION
Create an account, database and container	Create an Azure Cosmos DB account, database and container.
Create an account, database and container with autoscale	Create an Azure Cosmos DB account, database and container with autoscale.
Create a container with a large partition key	Create a container with a large partition key.
Create a container with no index policy	Create an Azure Cosmos container with index policy turned off.
List or get databases or containers	List or get database or containers.

TASK	DESCRIPTION
Throughput operations	Throughput operations for a database or container including get, update and migrate between autoscale and standard throughput.
Lock resources from deletion	Prevent resources from being deleted with resource locks.

Azure CLI samples for Azure Cosmos DB Core (SQL) API

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The following table includes links to sample Azure CLI scripts for Azure Cosmos DB. Use the links on the right to navigate to API specific samples. Common samples are the same across all APIs. Reference pages for all Azure Cosmos DB CLI commands are available in the Azure CLI Reference. Azure Cosmos DB CLI script samples can also be found in the Azure Cosmos DB CLI GitHub Repository.

These samples require Azure CLI version 2.12.1 or later. Run `az --version` to find the version. If you need to install or upgrade, see Install Azure CLI

For Azure CLI samples for other APIs see CLI Samples for Cassandra, CLI Samples for MongoDB API, CLI Samples for Gremlin, CLI Samples for Table

Common Samples

These samples apply to all Azure Cosmos DB APIs

TASK	DESCRIPTION
Add or failover regions	Add a region, change failover priority, trigger a manual failover.
Account keys and connection strings	List account keys, read-only keys, regenerate keys and list connection strings.
Secure with IP firewall	Create a Cosmos account with IP firewall configured.
Secure new account with service endpoints	Create a Cosmos account and secure with service-endpoints.
Secure existing account with service endpoints	Update a Cosmos account to secure with service-endpoints when the subnet is eventually configured.

Core (SQL) API Samples

TASK	DESCRIPTION
Create an Azure Cosmos account, database and container	Creates an Azure Cosmos DB account, database, and container for Core (SQL) API.
Create an Azure Cosmos account, database and container with autoscale	Creates an Azure Cosmos DB account, database, and container with autoscale for Core (SQL) API.
Throughput operations	Read, update and migrate between autoscale and standard throughput on a database and container.

TASK	DESCRIPTION
Lock resources from deletion	Prevent resources from being deleted with resource locks.

Azure Resource Manager templates for Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article only shows Azure Resource Manager template examples for Core (SQL) API accounts. You can also find template examples for Cassandra, Gremlin, MongoDB, and Table APIs.

Core (SQL) API

TEMPLATE	DESCRIPTION
Create an Azure Cosmos account, database, container with autoscale throughput	This template creates a Core (SQL) API account in two regions, a database and container with autoscale throughput.
Create an Azure Cosmos account, database, container with analytical store	This template creates a Core (SQL) API account in one region with a container configured with Analytical TTL enabled and option to use manual or autoscale throughput.
Create an Azure Cosmos account, database, container with standard (manual) throughput	This template creates a Core (SQL) API account in two regions, a database and container with standard throughput.
Create an Azure Cosmos account, database and container with a stored procedure, trigger and UDF	This template creates a Core (SQL) API account in two regions with a stored procedure, trigger and UDF for a container.
Create a private endpoint for an existing Azure Cosmos account	This template creates a private endpoint for an existing Azure Cosmos Core (SQL) API account in an existing virtual network.
Create a free-tier Azure Cosmos account	This template creates an Azure Cosmos DB Core (SQL) API account on free-tier.

See Azure Resource Manager reference for Azure Cosmos DB page for the reference documentation.

Data modeling in Azure Cosmos DB

12/4/2020 • 14 minutes to read • Edit Online

APPLIES TO: SQL API

While schema-free databases, like Azure Cosmos DB, make it super easy to store and query unstructured and semi-structured data, you should spend some time thinking about your data model to get the most of the service in terms of performance and scalability and lowest cost.

How is data going to be stored? How is your application going to retrieve and query data? Is your application read-heavy, or write-heavy?

After reading this article, you will be able to answer the following questions:

- What is data modeling and why should I care?
- How is modeling data in Azure Cosmos DB different to a relational database?
- How do I express data relationships in a non-relational database?
- When do I embed data and when do I link to data?

Embedding data

When you start modeling data in Azure Cosmos DB try to treat your entities as **self-contained items** represented as JSON documents.

For comparison, let's first see how we might model data in a relational database. The following example shows how a person might be stored in a relational database.

When working with relational databases, the strategy is to normalize all your data. Normalizing your data typically involves taking an entity, such as a person, and breaking it down into discrete components. In the example above, a person can have multiple contact detail records, as well as multiple address records. Contact details can be further broken down by further extracting common fields like a type. The same applies to address, each record can be of type *Home* or *Business*.

The guiding premise when normalizing data is to **avoid storing redundant data** on each record and rather refer to data. In this example, to read a person, with all their contact details and addresses, you need to use JOINS to effectively compose back (or denormalize) your data at run time.

```
SELECT p.FirstName, p.LastName, a.City, cd.Detail
FROM Person p
JOIN ContactDetail cd ON cd.PersonId = p.Id
JOIN ContactDetailType cdt ON cdt.Id = cd.TypeId
JOIN Address a ON a.PersonId = p.Id
```

Updating a single person with their contact details and addresses requires write operations across many individual tables.

Now let's take a look at how we would model the same data as a self-contained entity in Azure Cosmos DB.

```
{
    "id": "1",
    "firstName": "Thomas",
    "lastName": "Andersen",
    "addresses": [
        {
            "line1": "100 Some Street",
            "line2": "Unit 1",
            "city": "Seattle",
            "state": "WA",
            "zip": 98012
        }
    ],
    "contactDetails": [
        {"email": "thomas@andersen.com"},
        {"phone": "+1 555 555-5555", "extension": 5555}
    ]
}
```

Using the approach above we have **denormalized** the person record, by **embedding** all the information related to this person, such as their contact details and addresses, into a *single JSON* document. In addition, because we're not confined to a fixed schema we have the flexibility to do things like having contact details of different shapes entirely.

Retrieving a complete person record from the database is now a **single read operation** against a single container and for a single item. Updating a person record, with their contact details and addresses, is also a **single write operation** against a single item.

By denormalizing data, your application may need to issue fewer queries and updates to complete common operations.

When to embed

In general, use embedded data models when:

- There are **contained** relationships between entities.
- There are **one-to-few** relationships between entities.
- There is embedded data that **changes infrequently**.
- There is embedded data that will not grow **without bound**.
- There is embedded data that is **queried frequently together**.

> **NOTE**
>
> Typically denormalized data models provide better **read** performance.

When not to embed

While the rule of thumb in Azure Cosmos DB is to denormalize everything and embed all data into a single item, this can lead to some situations that should be avoided.

Take this JSON snippet.

```
{
    "id": "1",
    "name": "What's new in the coolest Cloud",
    "summary": "A blog post by someone real famous",
    "comments": [
        {"id": 1, "author": "anon", "comment": "something useful, I'm sure"},
        {"id": 2, "author": "bob", "comment": "wisdom from the interwebs"},
        …
        {"id": 100001, "author": "jane", "comment": "and on we go ..."},
        …
        {"id": 1000000001, "author": "angry", "comment": "blah angry blah angry"},
        …
        {"id": ∞ + 1, "author": "bored", "comment": "oh man, will this ever end?"},
    ]
}
```

This might be what a post entity with embedded comments would look like if we were modeling a typical blog, or CMS, system. The problem with this example is that the comments array is **unbounded**, meaning that there is no (practical) limit to the number of comments any single post can have. This may become a problem as the size of the item could grow infinitely large.

As the size of the item grows the ability to transmit the data over the wire as well as reading and updating the item, at scale, will be impacted.

In this case, it would be better to consider the following data model.

```
Post item:
{
    "id": "1",
    "name": "What's new in the coolest Cloud",
    "summary": "A blog post by someone real famous",
    "recentComments": [
        {"id": 1, "author": "anon", "comment": "something useful, I'm sure"},
        {"id": 2, "author": "bob", "comment": "wisdom from the interwebs"},
        {"id": 3, "author": "jane", "comment": "....."}
    ]
}

Comment items:
{
    "postId": "1"
    "comments": [
        {"id": 4, "author": "anon", "comment": "more goodness"},
        {"id": 5, "author": "bob", "comment": "tails from the field"},
        ...
        {"id": 99, "author": "angry", "comment": "blah angry blah angry"}
    ]
},
{
    "postId": "1"
    "comments": [
        {"id": 100, "author": "anon", "comment": "yet more"},
        ...
        {"id": 199, "author": "bored", "comment": "will this ever end?"}
    ]
}
```

This model has the three most recent comments embedded in the post container, which is an array with a fixed set of attributes. The other comments are grouped in to batches of 100 comments and stored as separate items. The size of the batch was chosen as 100 because our fictitious application allows the user to load 100 comments at a time.

Another case where embedding data is not a good idea is when the embedded data is used often across items and will change frequently.

Take this JSON snippet.

```
{
    "id": "1",
    "firstName": "Thomas",
    "lastName": "Andersen",
    "holdings": [
        {
            "numberHeld": 100,
            "stock": { "symbol": "zaza", "open": 1, "high": 2, "low": 0.5 }
        },
        {
            "numberHeld": 50,
            "stock": { "symbol": "xcxc", "open": 89, "high": 93.24, "low": 88.87 }
        }
    ]
}
```

This could represent a person's stock portfolio. We have chosen to embed the stock information into each portfolio document. In an environment where related data is changing frequently, like a stock trading application, embedding data that changes frequently is going to mean that you are constantly updating each portfolio document every time a stock is traded.

Stock *zaza* may be traded many hundreds of times in a single day and thousands of users could have *zaza* on their portfolio. With a data model like the above we would have to update many thousands of portfolio documents many times every day leading to a system that won't scale well.

Referencing data

Embedding data works nicely for many cases but there are scenarios when denormalizing your data will cause more problems than it is worth. So what do we do now?

Relational databases are not the only place where you can create relationships between entities. In a document database, you can have information in one document that relates to data in other documents. We do not recommend building systems that would be better suited to a relational database in Azure Cosmos DB, or any other document database, but simple relationships are fine and can be useful.

In the JSON below we chose to use the example of a stock portfolio from earlier but this time we refer to the stock item on the portfolio instead of embedding it. This way, when the stock item changes frequently throughout the day the only document that needs to be updated is the single stock document.

```
Person document:
{
    "id": "1",
    "firstName": "Thomas",
    "lastName": "Andersen",
    "holdings": [
        { "numberHeld":  100, "stockId": 1},
        { "numberHeld":  50, "stockId": 2}
    ]
}

Stock documents:
{
    "id": "1",
    "symbol": "zaza",
    "open": 1,
    "high": 2,
    "low": 0.5,
    "vol": 11970000,
    "mkt-cap": 42000000,
    "pe": 5.89
},
{
    "id": "2",
    "symbol": "xcxc",
    "open": 89,
    "high": 93.24,
    "low": 88.87,
    "vol": 2970200,
    "mkt-cap": 1005000,
    "pe": 75.82
}
```

An immediate downside to this approach though is if your application is required to show information about each stock that is held when displaying a person's portfolio; in this case you would need to make multiple trips to the database to load the information for each stock document. Here we've made a decision to improve the efficiency of write operations, which happen frequently throughout the day, but in turn compromised on the read operations that potentially have less impact on the performance of this particular system.

> **NOTE**
>
> Normalized data models **can require more round trips** to the server.

What about foreign keys?

Because there is currently no concept of a constraint, foreign-key or otherwise, any inter-document relationships that you have in documents are effectively "weak links" and will not be verified by the database itself. If you want to ensure that the data a document is referring to actually exists, then you need to do this in your application, or through the use of server-side triggers or stored procedures on Azure Cosmos DB.

When to reference

In general, use normalized data models when:

- Representing **one-to-many** relationships.
- Representing **many-to-many** relationships.
- Related data **changes frequently**.
- Referenced data could be **unbounded**.

> **NOTE**
> Typically normalizing provides better **write** performance.

Where do I put the relationship?

The growth of the relationship will help determine in which document to store the reference.

If we look at the JSON below that models publishers and books.

```
Publisher document:
{
    "id": "mspress",
    "name": "Microsoft Press",
    "books": [ 1, 2, 3, ..., 100, ..., 1000]
}

Book documents:
{"id": "1", "name": "Azure Cosmos DB 101" }
{"id": "2", "name": "Azure Cosmos DB for RDBMS Users" }
{"id": "3", "name": "Taking over the world one JSON doc at a time" }
...
{"id": "100", "name": "Learn about Azure Cosmos DB" }
...
{"id": "1000", "name": "Deep Dive into Azure Cosmos DB" }
```

If the number of the books per publisher is small with limited growth, then storing the book reference inside the publisher document may be useful. However, if the number of books per publisher is unbounded, then this data model would lead to mutable, growing arrays, as in the example publisher document above.

Switching things around a bit would result in a model that still represents the same data but now avoids these large mutable collections.

```
Publisher document:
{
    "id": "mspress",
    "name": "Microsoft Press"
}

Book documents:
{"id": "1","name": "Azure Cosmos DB 101", "pub-id": "mspress"}
{"id": "2","name": "Azure Cosmos DB for RDBMS Users", "pub-id": "mspress"}
{"id": "3","name": "Taking over the world one JSON doc at a time"}
...
{"id": "100","name": "Learn about Azure Cosmos DB", "pub-id": "mspress"}
...
{"id": "1000","name": "Deep Dive into Azure Cosmos DB", "pub-id": "mspress"}
```

In the above example, we have dropped the unbounded collection on the publisher document. Instead we just have a reference to the publisher on each book document.

How do I model many:many relationships?

In a relational database *many:many* relationships are often modeled with join tables, which just join records from other tables together.

You might be tempted to replicate the same thing using documents and produce a data model that looks similar to the following.

```
Author documents:
{"id": "a1", "name": "Thomas Andersen" }
{"id": "a2", "name": "William Wakefield" }

Book documents:
{"id": "b1", "name": "Azure Cosmos DB 101" }
{"id": "b2", "name": "Azure Cosmos DB for RDBMS Users" }
{"id": "b3", "name": "Taking over the world one JSON doc at a time" }
{"id": "b4", "name": "Learn about Azure Cosmos DB" }
{"id": "b5", "name": "Deep Dive into Azure Cosmos DB" }

Joining documents:
{"authorId": "a1", "bookId": "b1" }
{"authorId": "a2", "bookId": "b1" }
{"authorId": "a1", "bookId": "b2" }
{"authorId": "a1", "bookId": "b3" }
```

This would work. However, loading either an author with their books, or loading a book with its author, would always require at least two additional queries against the database. One query to the joining document and then another query to fetch the actual document being joined.

If all this join table is doing is gluing together two pieces of data, then why not drop it completely? Consider the following.

```
Author documents:
{"id": "a1", "name": "Thomas Andersen", "books": ["b1", "b2", "b3"]}
{"id": "a2", "name": "William Wakefield", "books": ["b1", "b4"]}

Book documents:
{"id": "b1", "name": "Azure Cosmos DB 101", "authors": ["a1", "a2"]}
{"id": "b2", "name": "Azure Cosmos DB for RDBMS Users", "authors": ["a1"]}
{"id": "b3", "name": "Learn about Azure Cosmos DB", "authors": ["a1"]}
{"id": "b4", "name": "Deep Dive into Azure Cosmos DB", "authors": ["a2"]}
```

Now, if I had an author, I immediately know which books they have written, and conversely if I had a book document loaded I would know the IDs of the author(s). This saves that intermediary query against the join table reducing the number of server round trips your application has to make.

Hybrid data models

We've now looked embedding (or denormalizing) and referencing (or normalizing) data, each have their upsides and each have compromises as we have seen.

It doesn't always have to be either or, don't be scared to mix things up a little.

Based on your application's specific usage patterns and workloads there may be cases where mixing embedded and referenced data makes sense and could lead to simpler application logic with fewer server round trips while still maintaining a good level of performance.

Consider the following JSON.

```
Author documents:
{
    "id": "a1",
    "firstName": "Thomas",
    "lastName": "Andersen",
    "countOfBooks": 3,
    "books": ["b1", "b2", "b3"],
    "images": [
        {"thumbnail": "https://....png"}
        {"profile": "https://....png"}
        {"large": "https://....png"}
    ]
},
{
    "id": "a2",
    "firstName": "William",
    "lastName": "Wakefield",
    "countOfBooks": 1,
    "books": ["b1"],
    "images": [
        {"thumbnail": "https://....png"}
    ]
}

Book documents:
{
    "id": "b1",
    "name": "Azure Cosmos DB 101",
    "authors": [
        {"id": "a1", "name": "Thomas Andersen", "thumbnailUrl": "https://....png"},
        {"id": "a2", "name": "William Wakefield", "thumbnailUrl": "https://....png"}
    ]
},
{
    "id": "b2",
    "name": "Azure Cosmos DB for RDBMS Users",
    "authors": [
        {"id": "a1", "name": "Thomas Andersen", "thumbnailUrl": "https://....png"},
    ]
}
```

Here we've (mostly) followed the embedded model, where data from other entities are embedded in the top-level document, but other data is referenced.

If you look at the book document, we can see a few interesting fields when we look at the array of authors. There is an `id` field that is the field we use to refer back to an author document, standard practice in a normalized model, but then we also have `name` and `thumbnailUrl`. We could have stuck with `id` and left the application to get any additional information it needed from the respective author document using the "link", but because our application displays the author's name and a thumbnail picture with every book displayed we can save a round trip to the server per book in a list by denormalizing **some** data from the author.

Sure, if the author's name changed or they wanted to update their photo we'd have to go and update every book they ever published but for our application, based on the assumption that authors don't change their names often, this is an acceptable design decision.

In the example, there are **pre-calculated aggregates** values to save expensive processing on a read operation. In the example, some of the data embedded in the author document is data that is calculated at run-time. Every time a new book is published, a book document is created **and** the countOfBooks field is set to a calculated value based on the number of book documents that exist for a particular author. This optimization would be good in read heavy systems where we can afford to do computations on writes in order to optimize reads.

The ability to have a model with pre-calculated fields is made possible because Azure Cosmos DB supports **multi-document transactions**. Many NoSQL stores cannot do transactions across documents and therefore advocate design decisions, such as "always embed everything", due to this limitation. With Azure Cosmos DB, you can use server-side triggers, or stored procedures, that insert books and update authors all within an ACID transaction. Now you don't **have** to embed everything into one document just to be sure that your data remains consistent.

Distinguishing between different document types

In some scenarios, you may want to mix different document types in the same collection; this is usually the case when you want multiple, related documents to sit in the same partition. For example, you could put both books and book reviews in the same collection and partition it by `bookId`. In such situation, you usually want to add to your documents with a field that identifies their type in order to differentiate them.

```
Book documents:
{
    "id": "b1",
    "name": "Azure Cosmos DB 101",
    "bookId": "b1",
    "type": "book"
}

Review documents:
{
    "id": "r1",
    "content": "This book is awesome",
    "bookId": "b1",
    "type": "review"
},
{
    "id": "r2",
    "content": "Best book ever!",
    "bookId": "b1",
    "type": "review"
}
```

Next steps

The biggest takeaways from this article are to understand that data modeling in a schema-free world is as important as ever.

Just as there is no single way to represent a piece of data on a screen, there is no single way to model your data. You need to understand your application and how it will produce, consume, and process the data. Then, by applying some of the guidelines presented here you can set about creating a model that addresses the immediate needs of your application. When your applications need to change, you can leverage the flexibility of a schema-free database to embrace that change and evolve your data model easily.

To learn more about Azure Cosmos DB, refer to the service's documentation page.

To understand how to shard your data across multiple partitions, refer to Partitioning Data in Azure Cosmos DB.

To learn how to model and partition data on Azure Cosmos DB using a real-world example, refer to Data Modeling and Partitioning - a Real-World Example.

How to model and partition data on Azure Cosmos DB using a real-world example

12/4/2020 • 17 minutes to read • Edit Online

APPLIES TO: SQL API

This article builds on several Azure Cosmos DB concepts like data modeling, partitioning, and provisioned throughput to demonstrate how to tackle a real-world data design exercise.

If you usually work with relational databases, you have probably built habits and intuitions on how to design a data model. Because of the specific constraints, but also the unique strengths of Azure Cosmos DB, most of these best practices don't translate well and may drag you into suboptimal solutions. The goal of this article is to guide you through the complete process of modeling a real-world use-case on Azure Cosmos DB, from item modeling to entity colocation and container partitioning.

Download or view a community-generated source code that illustrates the concepts from this article. This code sample was contributed by a community contributor and Azure Cosmos DB team doesn't support its maintenance.

The scenario

For this exercise, we are going to consider the domain of a blogging platform where *users* can create *posts*. Users can also *like* and add *comments* to those posts.

> **TIP**
> We have highlighted some words in *italic*, these words identify the kind of "things" our model will have to manipulate.

Adding more requirements to our specification:

- A front page displays a feed of recently created posts,
- We can fetch all posts for a user, all comments for a post and all likes for a post,
- Posts are returned with the username of their authors and a count of how many comments and likes they have,
- Comments and likes are also returned with the username of the users who have created them,
- When displayed as lists, posts only have to present a truncated summary of their content.

Identify the main access patterns

To start, we give some structure to our initial specification by identifying our solution's access patterns. When designing a data model for Azure Cosmos DB, it's important to understand which requests our model will have to serve to make sure that the model will serve those requests efficiently.

To make the overall process easier to follow, we categorize those different requests as either commands or queries, borrowing some vocabulary from CQRS where commands are write requests (that is, intents to update the system) and queries are read-only requests.

Here is the list of requests that our platform will have to expose:

- **[C1]** Create/edit a user
- **[Q1]** Retrieve a user
- **[C2]** Create/edit a post

- **[Q2]** Retrieve a post
- **[Q3]** List a user's posts in short form
- **[C3]** Create a comment
- **[Q4]** List a post's comments
- **[C4]** Like a post
- **[Q5]** List a post's likes
- **[Q6]** List the *x* most recent posts created in short form (feed)

At this stage, we haven't thought about the details of what each entity (user, post etc.) will contain. This step is usually among the first ones to be tackled when designing against a relational store, because we have to figure out how those entities will translate in terms of tables, columns, foreign keys etc. It is much less of a concern with a document database that doesn't enforce any schema at write.

The main reason why it is important to identify our access patterns from the beginning, is because this list of requests is going to be our test suite. Every time we iterate over our data model, we will go through each of the requests and check its performance and scalability.

V1: A first version

We start with two containers: `users` and `posts`.

Users container

This container only stores user items:

```
{
    "id": "<user-id>",
    "username": "<username>"
}
```

We partition this container by `id`, which means that each logical partition within that container will only contain one item.

Posts container

This container hosts posts, comments, and likes:

```
{
    "id": "<post-id>",
    "type": "post",
    "postId": "<post-id>",
    "userId": "<post-author-id>",
    "title": "<post-title>",
    "content": "<post-content>",
    "creationDate": "<post-creation-date>"
}

{
    "id": "<comment-id>",
    "type": "comment",
    "postId": "<post-id>",
    "userId": "<comment-author-id>",
    "content": "<comment-content>",
    "creationDate": "<comment-creation-date>"
}

{
    "id": "<like-id>",
    "type": "like",
    "postId": "<post-id>",
    "userId": "<liker-id>",
    "creationDate": "<like-creation-date>"
}
```

We partition this container by `postId`, which means that each logical partition within that container will contain one post, all the comments for that post and all the likes for that post.

Note that we have introduced a `type` property in the items stored in this container to distinguish between the three types of entities that this container hosts.

Also, we have chosen to reference related data instead of embedding it (check this section for details about these concepts) because:

- there's no upper limit to how many posts a user can create,
- posts can be arbitrarily long,
- there's no upper limit to how many comments and likes a post can have,
- we want to be able to add a comment or a like to a post without having to update the post itself.

How well does our model perform?

It's now time to assess the performance and scalability of our first version. For each of the requests previously identified, we measure its latency and how many request units it consumes. This measurement is done against a dummy data set containing 100,000 users with 5 to 50 posts per user, and up to 25 comments and 100 likes per post.

[C1] Create/edit a user

This request is straightforward to implement as we just create or update an item in the `users` container. The requests will nicely spread across all partitions thanks to the `id` partition key.

LATENCY	RU CHARGE	PERFORMANCE
7 ms	5.71 RU	✅

[Q1] Retrieve a user

Retrieving a user is done by reading the corresponding item from the `users` container.

LATENCY	RU CHARGE	PERFORMANCE
2 ms	1 RU	✅

[C2] Create/edit a post

Similarly to **[C1]**, we just have to write to the `posts` container.

LATENCY	RU CHARGE	PERFORMANCE
9 ms	8.76 RU	✅

[Q2] Retrieve a post

We start by retrieving the corresponding document from the `posts` container. But that's not enough, as per our specification we also have to aggregate the username of the post's author and the counts of how many comments and how many likes this post has, which requires 3 additional SQL queries to be issued.

Each of the additional queries filters on the partition key of its respective container, which is exactly what we want to maximize performance and scalability. But we eventually have to perform four operations to return a single post, so we'll improve that in a next iteration.

LATENCY	RU CHARGE	PERFORMANCE
9 ms	19.54 RU	⚠

[Q3] List a user's posts in short form

First, we have to retrieve the desired posts with a SQL query that fetches the posts corresponding to that particular user. But we also have to issue additional queries to aggregate the author's username and the counts of comments and likes.

This implementation presents many drawbacks:

- the queries aggregating the counts of comments and likes have to be issued for each post returned by the first query,
- the main query does not filter on the partition key of the `posts` container, leading to a fan-out and a partition scan across the container.

LATENCY	RU CHARGE	PERFORMANCE
130 ms	619.41 RU	⚠

[C3] Create a comment

A comment is created by writing the corresponding item in the `posts` container.

LATENCY	RU CHARGE	PERFORMANCE
7 ms	8.57 RU	☑

[Q4] List a post's comments

We start with a query that fetches all the comments for that post and once again, we also need to aggregate usernames separately for each comment.

Although the main query does filter on the container's partition key, aggregating the usernames separately penalizes the overall performance. We'll improve that later on.

LATENCY	RU CHARGE	PERFORMANCE
23 ms	27.72 RU	⚠

[C4] Like a post

Just like **[C3]**, we create the corresponding item in the `posts` container.

LATENCY	RU CHARGE	PERFORMANCE
6 ms	7.05 RU	☑

[Q5] List a post's likes

Just like **[Q4]**, we query the likes for that post, then aggregate their usernames.

LATENCY	RU CHARGE	PERFORMANCE
59 ms	58.92 RU	⚠

[Q6] List the x most recent posts created in short form (feed)

We fetch the most recent posts by querying the `posts` container sorted by descending creation date, then aggregate usernames and counts of comments and likes for each of the posts.

Once again, our initial query doesn't filter on the partition key of the `posts` container, which triggers a costly fan-out. This one is even worse as we target a much larger result set and sort the results with an `ORDER BY` clause, which makes it more expensive in terms of request units.

LATENCY	RU CHARGE	PERFORMANCE
306 ms	2063.54 RU	⚠

Reflecting on the performance of V1

Looking at the performance issues we faced in the previous section, we can identify two main classes of problems:

- some requests require multiple queries to be issued in order to gather all the data we need to return,
- some queries don't filter on the partition key of the containers they target, leading to a fan-out that impedes our scalability.

Let's resolve each of those problems, starting with the first one.

V2: Introducing denormalization to optimize read queries

The reason why we have to issue additional requests in some cases is because the results of the initial request doesn't contain all the data we need to return. When working with a non-relational data store like Azure Cosmos DB, this kind of issue is commonly solved by denormalizing data across our data set.

In our example, we modify post items to add the username of the post's author, the count of comments and the count of likes:

```
{
    "id": "<post-id>",
    "type": "post",
    "postId": "<post-id>",
    "userId": "<post-author-id>",
    "userUsername": "<post-author-username>",
    "title": "<post-title>",
    "content": "<post-content>",
    "commentCount": <count-of-comments>,
    "likeCount": <count-of-likes>,
    "creationDate": "<post-creation-date>"
}
```

We also modify comment and like items to add the username of the user who has created them:

```
{
    "id": "<comment-id>",
    "type": "comment",
    "postId": "<post-id>",
    "userId": "<comment-author-id>",
    "userUsername": "<comment-author-username>",
    "content": "<comment-content>",
    "creationDate": "<comment-creation-date>"
}

{
    "id": "<like-id>",
    "type": "like",
    "postId": "<post-id>",
    "userId": "<liker-id>",
    "userUsername": "<liker-username>",
    "creationDate": "<like-creation-date>"
}
```

Denormalizing comment and like counts

What we want to achieve is that every time we add a comment or a like, we also increment the `commentCount` or the `likeCount` in the corresponding post. As our `posts` container is partitioned by `postId`, the new item (comment or like) and its corresponding post sit in the same logical partition. As a result, we can use a stored procedure to perform that operation.

Now when creating a comment ([C3]), instead of just adding a new item in the `posts` container we call the following stored procedure on that container:

```
function createComment(postId, comment) {
  var collection = getContext().getCollection();

  collection.readDocument(
    `${collection.getAltLink()}/docs/${postId}`,
    function (err, post) {
      if (err) throw err;

      post.commentCount++;
      collection.replaceDocument(
        post._self,
        post,
        function (err) {
          if (err) throw err;

          comment.postId = postId;
          collection.createDocument(
            collection.getSelfLink(),
            comment
          );
        }
      );
    })
}
```

This stored procedure takes the ID of the post and the body of the new comment as parameters, then:

- retrieves the post
- increments the `commentCount`
- replaces the post
- adds the new comment

As stored procedures are executed as atomic transactions, the value of `commentCount` and the actual number of comments will always stay in sync.

We obviously call a similar stored procedure when adding new likes to increment the `likeCount`.

Denormalizing usernames

Usernames require a different approach as users not only sit in different partitions, but in a different container. When we have to denormalize data across partitions and containers, we can use the source container's change feed.

In our example, we use the change feed of the `users` container to react whenever users update their usernames. When that happens, we propagate the change by calling another stored procedure on the `posts` container:

```
function updateUsernames(userId, username) {
  var collection = getContext().getCollection();

  collection.queryDocuments(
    collection.getSelfLink(),
    `SELECT * FROM p WHERE p.userId = '${userId}'`,
    function (err, results) {
      if (err) throw err;

      for (var i in results) {
        var doc = results[i];
        doc.userUsername = username;

        collection.upsertDocument(
          collection.getSelfLink(),
          doc);
      }
    });
}
```

This stored procedure takes the ID of the user and the user's new username as parameters, then:

- fetches all items matching the `userId` (which can be posts, comments, or likes)
- for each of those items
  - replaces the `userUsername`
  - replaces the item

> **IMPORTANT**
> This operation is costly because it requires this stored procedure to be executed on every partition of the `posts` container. We assume that most users choose a suitable username during sign-up and won't ever change it, so this update will run very rarely.

What are the performance gains of V2?

[Q2] Retrieve a post

Now that our denormalization is in place, we only have to fetch a single item to handle that request.

LATENCY	RU CHARGE	PERFORMANCE
2 ms	1 RU	☑

[Q4] List a post's comments

Here again, we can spare the extra requests that fetched the usernames and end up with a single query that filters on the partition key.

LATENCY	RU CHARGE	PERFORMANCE
4 ms	7.72 RU	☑

[Q5] List a post's likes

Exact same situation when listing the likes.

LATENCY	RU CHARGE	PERFORMANCE
4 ms	8.92 RU	☑

V3: Making sure all requests are scalable

Looking at our overall performance improvements, there are still two requests that we haven't fully optimized: **[Q3]** and **[Q6]**. They are the requests involving queries that don't filter on the partition key of the containers they target.

[Q3] List a user's posts in short form

This request already benefits from the improvements introduced in V2, which spares additional queries.

But the remaining query is still not filtering on the partition key of the `posts` container.

The way to think about this situation is actually simple:

1. This request *has* to filter on the `userId` because we want to fetch all posts for a particular user
2. It doesn't perform well because it is executed against the `posts` container, which is not partitioned by `userId`
3. Stating the obvious, we would solve our performance problem by executing this request against a container that *is* partitioned by `userId`
4. It turns out that we already have such a container: the `users` container!

So we introduce a second level of denormalization by duplicating entire posts to the `users` container. By doing that, we effectively get a copy of our posts, only partitioned along a different dimensions, making them way more efficient to retrieve by their `userId`.

The `users` container now contains 2 kinds of items:

```
{
    "id": "<user-id>",
    "type": "user",
    "userId": "<user-id>",
    "username": "<username>"
}

{
    "id": "<post-id>",
    "type": "post",
    "postId": "<post-id>",
    "userId": "<post-author-id>",
    "userUsername": "<post-author-username>",
    "title": "<post-title>",
    "content": "<post-content>",
    "commentCount": <count-of-comments>,
    "likeCount": <count-of-likes>,
    "creationDate": "<post-creation-date>"
}
```

Note that:

- we have introduced a `type` field in the user item to distinguish users from posts,
- we have also added a `userId` field in the user item, which is redundant with the `id` field but is required as the `users` container is now partitioned by `userId` (and not `id` as previously)

To achieve that denormalization, we once again use the change feed. This time, we react on the change feed of the `posts` container to dispatch any new or updated post to the `users` container. And because listing posts does not require to return their full content, we can truncate them in the process.

We can now route our query to the `users` container, filtering on the container's partition key.

LATENCY	RU CHARGE	PERFORMANCE
4 ms	6.46 RU	☑

[Q6] List the x most recent posts created in short form (feed)

We have to deal with a similar situation here: even after sparing the additional queries left unnecessary by the denormalization introduced in V2, the remaining query does not filter on the container's partition key:

Following the same approach, maximizing this request's performance and scalability requires that it only hits one partition. This is conceivable because we only have to return a limited number of items; in order to populate our blogging platform's home page, we just need to get the 100 most recent posts, without the need to paginate through the entire data set.

So to optimize this last request, we introduce a third container to our design, entirely dedicated to serving this

request. We denormalize our posts to that new `feed` container:

```
{
    "id": "<post-id>",
    "type": "post",
    "postId": "<post-id>",
    "userId": "<post-author-id>",
    "userUsername": "<post-author-username>",
    "title": "<post-title>",
    "content": "<post-content>",
    "commentCount": <count-of-comments>,
    "likeCount": <count-of-likes>,
    "creationDate": "<post-creation-date>"
}
```

This container is partitioned by `type`, which will always be `post` in our items. Doing that ensures that all the items in this container will sit in the same partition.

To achieve the denormalization, we just have to hook on the change feed pipeline we have previously introduced to dispatch the posts to that new container. One important thing to bear in mind is that we need to make sure that we only store the 100 most recent posts; otherwise, the content of the container may grow beyond the maximum size of a partition. This is done by calling a post-trigger every time a document is added in the container:

Here's the body of the post-trigger that truncates the collection:

```
function truncateFeed() {
  const maxDocs = 100;
  var context = getContext();
  var collection = context.getCollection();

  collection.queryDocuments(
    collection.getSelfLink(),
    "SELECT VALUE COUNT(1) FROM f",
    function (err, results) {
      if (err) throw err;

      processCountResults(results);
    });

  function processCountResults(results) {
    // + 1 because the query didn't count the newly inserted doc
    if ((results[0] + 1) > maxDocs) {
      var docsToRemove = results[0] + 1 - maxDocs;
      collection.queryDocuments(
        collection.getSelfLink(),
        `SELECT TOP ${docsToRemove} * FROM f ORDER BY f.creationDate`,
        function (err, results) {
          if (err) throw err;

          processDocsToRemove(results, 0);
        });
    }
  }

  function processDocsToRemove(results, index) {
    var doc = results[index];
    if (doc) {
      collection.deleteDocument(
        doc._self,
        function (err) {
          if (err) throw err;

          processDocsToRemove(results, index + 1);
        });
    }
  }
}
```

The final step is to reroute our query to our new `feed` container:

LATENCY	RU CHARGE	PERFORMANCE
9 ms	16.97 RU	☑

Conclusion

Let's have a look at the overall performance and scalability improvements we have introduced over the different

versions of our design.

	V1	V2	V3
[C1]	7 ms / 5.71 RU	7 ms / 5.71 RU	7 ms / 5.71 RU
[Q1]	2 ms / 1 RU	2 ms / 1 RU	2 ms / 1 RU
[C2]	9 ms / 8.76 RU	9 ms / 8.76 RU	9 ms / 8.76 RU
[Q2]	9 ms / 19.54 RU	2 ms / 1 RU	2 ms / 1 RU
[Q3]	130 ms / 619.41 RU	28 ms / 201.54 RU	4 ms / 6.46 RU
[C3]	7 ms / 8.57 RU	7 ms / 15.27 RU	7 ms / 15.27 RU
[Q4]	23 ms / 27.72 RU	4 ms / 7.72 RU	4 ms / 7.72 RU
[C4]	6 ms / 7.05 RU	7 ms / 14.67 RU	7 ms / 14.67 RU
[Q5]	59 ms / 58.92 RU	4 ms / 8.92 RU	4 ms / 8.92 RU
[Q6]	306 ms / 2063.54 RU	83 ms / 532.33 RU	9 ms / 16.97 RU

We have optimized a read-heavy scenario

You may have noticed that we have concentrated our efforts towards improving the performance of read requests (queries) at the expense of write requests (commands). In many cases, write operations now trigger subsequent denormalization through change feeds, which makes them more computationally expensive and longer to materialize.

This is justified by the fact that a blogging platform (like most social apps) is read-heavy, which means that the amount of read requests it has to serve is usually orders of magnitude higher than the amount of write requests. So it makes sense to make write requests more expensive to execute in order to let read requests be cheaper and better performing.

If we look at the most extreme optimization we have done, **[Q6]** went from 2000+ RUs to just 17 RUs; we have achieved that by denormalizing posts at a cost of around 10 RUs per item. As we would serve a lot more feed requests than creation or updates of posts, the cost of this denormalization is negligible considering the overall savings.

Denormalization can be applied incrementally

The scalability improvements we've explored in this article involve denormalization and duplication of data across the data set. It should be noted that these optimizations don't have to be put in place at day 1. Queries that filter on partition keys perform better at scale, but cross-partition queries can be totally acceptable if they are called rarely or against a limited data set. If you're just building a prototype, or launching a product with a small and controlled user base, you can probably spare those improvements for later; what's important then is to monitor your model's performance so you can decide if and when it's time to bring them in.

The change feed that we use to distribute updates to other containers store all those updates persistently. This makes it possible to request all updates since the creation of the container and bootstrap denormalized views as a one-time catch-up operation even if your system already has a lot of data.

Next steps

After this introduction to practical data modeling and partitioning, you may want to check the following articles to review the concepts we have covered:

Create a synthetic partition key

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

It's the best practice to have a partition key with many distinct values, such as hundreds or thousands. The goal is to distribute your data and workload evenly across the items associated with these partition key values. If such a property doesn't exist in your data, you can construct a *synthetic partition key*. This document describes several basic techniques for generating a synthetic partition key for your Cosmos container.

Concatenate multiple properties of an item

You can form a partition key by concatenating multiple property values into a single artificial `partitionKey` property. These keys are referred to as synthetic keys. For example, consider the following example document:

```
{
"deviceId": "abc-123",
"date": 2018
}
```

For the previous document, one option is to set /deviceId or /date as the partition key. Use this option, if you want to partition your container based on either device ID or date. Another option is to concatenate these two values into a synthetic `partitionKey` property that's used as the partition key.

```
{
"deviceId": "abc-123",
"date": 2018,
"partitionKey": "abc-123-2018"
}
```

In real-time scenarios, you can have thousands of items in a database. Instead of adding the synthetic key manually, define client-side logic to concatenate values and insert the synthetic key into the items in your Cosmos containers.

Use a partition key with a random suffix

Another possible strategy to distribute the workload more evenly is to append a random number at the end of the partition key value. When you distribute items in this way, you can perform parallel write operations across partitions.

An example is if a partition key represents a date. You might choose a random number between 1 and 400 and concatenate it as a suffix to the date. This method results in partition key values like `2018-08-09.1`, `2018-08-09.2`, and so on, through `2018-08-09.400`. Because you randomize the partition key, the write operations on the container on each day are spread evenly across multiple partitions. This method results in better parallelism and overall higher throughput.

Use a partition key with pre-calculated suffixes

The random suffix strategy can greatly improve write throughput, but it's difficult to read a specific item. You don't know the suffix value that was used when you wrote the item. To make it easier to read individual items, use the pre-calculated suffixes strategy. Instead of using a random number to distribute the items among the partitions,

use a number that is calculated based on something that you want to query.

Consider the previous example, where a container uses a date as the partition key. Now suppose that each item has a `Vehicle-Identification-Number` (`VIN`) attribute that we want to access. Further, suppose that you often run queries to find items by the `VIN`, in addition to date. Before your application writes the item to the container, it can calculate a hash suffix based on the VIN and append it to the partition key date. The calculation might generate a number between 1 and 400 that is evenly distributed. This result is similar to the results produced by the random suffix strategy method. The partition key value is then the date concatenated with the calculated result.

With this strategy, the writes are evenly spread across the partition key values, and across the partitions. You can easily read a particular item and date, because you can calculate the partition key value for a specific `Vehicle-Identification-Number`. The benefit of this method is that you can avoid creating a single hot partition key, i.e., a partition key that takes all the workload.

Next steps

Getting started with SQL queries

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

In Azure Cosmos DB SQL API accounts, there are two ways to read data:

Point reads - You can do a key/value lookup on a single *item ID* and partition key. The *item ID* and partition key combination is the key and the item itself is the value. For a 1 KB document, point reads typically cost 1 request unit with a latency under 10 ms. Point reads return a single item.

Here are some examples of how to do **Point reads** with each SDK:

- .NET SDK
- Java SDK
- Node.js SDK
- Python SDK

SQL queries - You can query data by writing queries using the Structured Query Language (SQL) as a JSON query language. Queries always cost at least 2.3 request units and, in general, will have a higher and more variable latency than point reads. Queries can return many items.

Most read-heavy workloads on Azure Cosmos DB use a combination of both point reads and SQL queries. If you just need to read a single item, point reads are cheaper and faster than queries. Point reads don't need to use the query engine to access data and can read the data directly. Of course, it's not possible for all workloads to exclusively read data using point reads, so support of SQL as a query language and schema-agnostic indexing provide a more flexible way to access your data.

Here are some examples of how to do **SQL queries** with each SDK:

- .NET SDK
- Java SDK
- Node.js SDK
- Python SDK

The remainder of this doc shows how to get started writing SQL queries in Azure Cosmos DB. SQL queries can be run through either the SDK or Azure portal.

Upload sample data

In your SQL API Cosmos DB account, open the Data Explorer to create a container called `Families`. After the it is created, use the data structures browser, to find and open it. In your `Families` container, you will see the `Items` option right below the name of the container. Open this option and you'll see a button, in the menu bar in center of the screen, to create a 'New Item'. You will use this feature to create the JSON items below.

Create JSON items

The following 2 JSON items are documents about the Andersen and Wakefield families. They include parents, children and their pets, address, and registration information.

The first item has strings, numbers, Booleans, arrays, and nested properties:

```
{
  "id": "AndersenFamily",
  "lastName": "Andersen",
  "parents": [
     { "firstName": "Thomas" },
     { "firstName": "Mary Kay"}
  ],
  "children": [
     {
         "firstName": "Henriette Thaulow",
         "gender": "female",
         "grade": 5,
         "pets": [{ "givenName": "Fluffy" }]
     }
  ],
  "address": { "state": "WA", "county": "King", "city": "Seattle" },
  "creationDate": 1431620472,
  "isRegistered": true
}
```

The second item uses `givenName` and `familyName` instead of `firstName` and `lastName`:

```
{
  "id": "WakefieldFamily",
  "parents": [
      { "familyName": "Wakefield", "givenName": "Robin" },
      { "familyName": "Miller", "givenName": "Ben" }
  ],
  "children": [
      {
        "familyName": "Merriam",
        "givenName": "Jesse",
        "gender": "female",
        "grade": 1,
        "pets": [
            { "givenName": "Goofy" },
            { "givenName": "Shadow" }
        ]
      },
      {
        "familyName": "Miller",
         "givenName": "Lisa",
         "gender": "female",
         "grade": 8 }
  ],
  "address": { "state": "NY", "county": "Manhattan", "city": "NY" },
  "creationDate": 1431620462,
  "isRegistered": false
}
```

Query the JSON items

Try a few queries against the JSON data to understand some of the key aspects of Azure Cosmos DB's SQL query language.

The following query returns the items where the `id` field matches `AndersenFamily`. Since it's a `SELECT *` query, the output of the query is the complete JSON item. For more information about SELECT syntax, see SELECT statement.

```
    SELECT *
    FROM Families f
    WHERE f.id = "AndersenFamily"
```

The query results are:

```
[{
    "id": "AndersenFamily",
    "lastName": "Andersen",
    "parents": [
       { "firstName": "Thomas" },
       { "firstName": "Mary Kay"}
    ],
    "children": [
       {
           "firstName": "Henriette Thaulow", "gender": "female", "grade": 5,
           "pets": [{ "givenName": "Fluffy" }]
       }
    ],
    "address": { "state": "WA", "county": "King", "city": "Seattle" },
    "creationDate": 1431620472,
    "isRegistered": true
}]
```

The following query reformats the JSON output into a different shape. The query projects a new JSON `Family` object with two selected fields, `Name` and `City`, when the address city is the same as the state. "NY, NY" matches this case.

```
SELECT {"Name":f.id, "City":f.address.city} AS Family
FROM Families f
WHERE f.address.city = f.address.state
```

The query results are:

```
[{
    "Family": {
        "Name": "WakefieldFamily",
        "City": "NY"
    }
}]
```

The following query returns all the given names of children in the family whose `id` matches `WakefieldFamily`, ordered by city.

```
SELECT c.givenName
FROM Families f
JOIN c IN f.children
WHERE f.id = 'WakefieldFamily'
ORDER BY f.address.city ASC
```

The results are:

```
[
  { "givenName": "Jesse" },
  { "givenName": "Lisa"}
]
```

Remarks

The preceding examples show several aspects of the Cosmos DB query language:

- Since SQL API works on JSON values, it deals with tree-shaped entities instead of rows and columns. You can refer to the tree nodes at any arbitrary depth, like `Node1.Node2.Node3…..Nodem`, similar to the two-part reference of `<table>.<column>` in ANSI SQL.
- Because the query language works with schemaless data, the type system must be bound dynamically. The same expression could yield different types on different items. The result of a query is a valid JSON value, but isn't guaranteed to be of a fixed schema.
- Azure Cosmos DB supports strict JSON items only. The type system and expressions are restricted to deal only with JSON types. For more information, see the JSON specification.
- A Cosmos container is a schema-free collection of JSON items. The relations within and across container items are implicitly captured by containment, not by primary key and foreign key relations. This feature is important for the intra-item joins discussed later in this article.

Next steps

- Introduction to Azure Cosmos DB
- Azure Cosmos DB .NET samples
- SELECT clause

SELECT clause in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Every query consists of a `SELECT` clause and optional FROM and WHERE clauses, per ANSI SQL standards. Typically, the source in the `FROM` clause is enumerated, and the `WHERE` clause applies a filter on the source to retrieve a subset of JSON items. The `SELECT` clause then projects the requested JSON values in the select list.

Syntax

```
SELECT <select_specification>

<select_specification> ::=
      '*'
      | [DISTINCT] <object_property_list>
      | [DISTINCT] VALUE <scalar_expression> [[ AS ] value_alias]

<object_property_list> ::=
{ <scalar_expression> [ [ AS ] property_alias ] } [ ,...n ]
```

Arguments

- `<select_specification>`

  Properties or value to be selected for the result set.

- `'*'`

  Specifies that the value should be retrieved without making any changes. Specifically if the processed value is an object, all properties will be retrieved.

- `<object_property_list>`

  Specifies the list of properties to be retrieved. Each returned value will be an object with the properties specified.

- `VALUE`

  Specifies that the JSON value should be retrieved instead of the complete JSON object. This, unlike `<property_list>` does not wrap the projected value in an object.

- `DISTINCT`

  Specifies that duplicates of projected properties should be removed.

- `<scalar_expression>`

  Expression representing the value to be computed. See Scalar expressions section for details.

Remarks

The `SELECT *` syntax is only valid if FROM clause has declared exactly one alias. `SELECT *` provides an identity projection, which can be useful if no projection is needed. SELECT * is only valid if FROM clause is specified and

introduced only a single input source.

Both `SELECT <select_list>` and `SELECT *` are "syntactic sugar" and can be alternatively expressed by using simple SELECT statements as shown below.

1. `SELECT * FROM ... AS from_alias ...`

   is equivalent to:

   `SELECT from_alias FROM ... AS from_alias ...`

2. `SELECT <expr1> AS p1, <expr2> AS p2,..., <exprN> AS pN [other clauses...]`

   is equivalent to:

   `SELECT VALUE { p1: <expr1>, p2: <expr2>, ..., pN: <exprN> }[other clauses...]`

Examples

The following SELECT query example returns `address` from `Families` whose `id` matches `AndersenFamily`:

```
SELECT f.address
FROM Families f
WHERE f.id = "AndersenFamily"
```

The results are:

```
[{
  "address": {
    "state": "WA",
    "county": "King",
    "city": "Seattle"
  }
}]
```

Next steps

- Getting started
- Azure Cosmos DB .NET samples
- WHERE clause

FROM clause in Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

The FROM (`FROM <from_specification>`) clause is optional, unless the source is filtered or projected later in the query. A query like `SELECT * FROM Families` enumerates over the entire `Families` container. You can also use the special identifier ROOT for the container instead of using the container name.

The `FROM` clause enforces the following rules per query:

- The container can be aliased, such as `SELECT f.id FROM Families AS f` or simply `SELECT f.id FROM Families f`. Here `f` is the alias for `Families`. AS is an optional keyword to alias the identifier.
- Once aliased, the original source name cannot be bound. For example, `SELECT Families.id FROM Families f` is syntactically invalid because the identifier `Families` has been aliased and can't be resolved anymore.
- All referenced properties must be fully qualified, to avoid any ambiguous bindings in the absence of strict schema adherence. For example, `SELECT id FROM Families f` is syntactically invalid because the property `id` isn't bound.

Syntax

```
FROM <from_specification>

<from_specification> ::=
        <from_source> {[ JOIN <from_source>][,...n]}

<from_source> ::=
          <container_expression> [[AS] input_alias]
        | input_alias IN <container_expression>

<container_expression> ::=
        ROOT
     | container_name
     | input_alias
     | <container_expression> '.' property_name
     | <container_expression> '[' "property_name" | array_index ']'
```

Arguments

- `<from_source>`

  Specifies a data source, with or without an alias. If alias is not specified, it will be inferred from the `<container_expression>` using following rules:

- If the expression is a container_name, then container_name will be used as an alias.
- If the expression is `<container_expression>`, then property_name, then property_name will be used as an alias. If the expression is a container_name, then container_name will be used as an alias.
- AS `input_alias`

  Specifies that the `input_alias` is a set of values returned by the underlying container expression.

- `input_alias` IN

  Specifies that the `input_alias` should represent the set of values obtained by iterating over all array elements of each array returned by the underlying container expression. Any value returned by underlying container expression that is not an array is ignored.

- `<container_expression>`

  Specifies the container expression to be used to retrieve the documents.

- `ROOT`

  Specifies that document should be retrieved from the default, currently connected container.

- `container_name`

  Specifies that document should be retrieved from the provided container. The name of the container must match the name of the container currently connected to.

- `input_alias`

  Specifies that document should be retrieved from the other source defined by the provided alias.

- `<container_expression> '.' property_name`

  Specifies that document should be retrieved by accessing the `property_name` property.

- `<container_expression> '[' "property_name" | array_index ']'`

  Specifies that document should be retrieved by accessing the `property_name` property or array_index array element for all documents retrieved by specified container expression.

Remarks

All aliases provided or inferred in the `<from_source>(` s) must be unique. The Syntax `<container_expression>.` property_name is the same as `<container_expression>' ['"property_name"']'`. However, the latter syntax can be used if a property name contains a non-identifier character.

Handling missing properties, missing array elements, and undefined values

If a container expression accesses properties or array elements and that value does not exist, that value will be ignored and not processed further.

Container expression context scoping

A container expression may be container-scoped or document-scoped:

- An expression is container-scoped, if the underlying source of the container expression is either ROOT or `container_name`. Such an expression represents a set of documents retrieved from the container directly, and is not dependent on the processing of other container expressions.

- An expression is document-scoped, if the underlying source of the container expression is `input_alias` introduced earlier in the query. Such an expression represents a set of documents obtained by evaluating the container expression in the scope of each document belonging to the set associated with the aliased container. The resulting set will be a union of sets obtained by evaluating the container expression for each of the documents in the underlying set.

Examples

Get subitems by using the FROM clause

The FROM clause can reduce the source to a smaller subset. To enumerate only a subtree in each item, the subroot

can become the source, as shown in the following example:

```
SELECT *
FROM Families.children
```

The results are:

```
[
  [
    {
        "firstName": "Henriette Thaulow",
        "gender": "female",
        "grade": 5,
        "pets": [
          {
              "givenName": "Fluffy"
          }
        ]
    }
  ],
  [
   {
        "familyName": "Merriam",
        "givenName": "Jesse",
        "gender": "female",
        "grade": 1
    },
    {
        "familyName": "Miller",
        "givenName": "Lisa",
        "gender": "female",
        "grade": 8
    }
  ]
]
```

The preceding query used an array as the source, but you can also use an object as the source. The query considers any valid, defined JSON value in the source for inclusion in the result. The following example would exclude `Families` that don't have an `address.state` value.

```
SELECT *
FROM Families.address.state
```

The results are:

```
[
  "WA",
  "NY"
]
```

Next steps

- Getting started
- SELECT clause
- WHERE clause

WHERE clause in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The optional WHERE clause (`WHERE <filter_condition>`) specifies condition(s) that the source JSON items must satisfy for the query to include them in results. A JSON item must evaluate the specified conditions to `true` to be considered for the result. The index layer uses the WHERE clause to determine the smallest subset of source items that can be part of the result.

Syntax

```
WHERE <filter_condition>
<filter_condition> ::= <scalar_expression>
```

Arguments

- `<filter_condition>`

  Specifies the condition to be met for the documents to be returned.

- `<scalar_expression>`

  Expression representing the value to be computed. See Scalar expressions for details.

Remarks

In order for the document to be returned an expression specified as filter condition must evaluate to true. Only Boolean value `true` will satisfy the condition, any other value: undefined, null, false, Number, Array, or Object will not satisfy the condition.

If you include your partition key in the `WHERE` clause as part of an equality filter, your query will automatically filter to only the relevant partitions.

Examples

The following query requests items that contain an `id` property whose value is `AndersenFamily`. It excludes any item that does not have an `id` property or whose value doesn't match `AndersenFamily`.

```
SELECT f.address
FROM Families f
WHERE f.id = "AndersenFamily"
```

The results are:

```
[{
  "address": {
    "state": "WA",
    "county": "King",
    "city": "Seattle"
  }
}]
```

Scalar expressions in the WHERE clause

The previous example showed a simple equality query. The SQL API also supports various scalar expressions. The most commonly used are binary and unary expressions. Property references from the source JSON object are also valid expressions.

You can use the following supported binary operators:

OPERATOR TYPE	VALUES
Arithmetic	+,-,*,/,%
Bitwise	|, &, ^, <<, >>, >>> (zero-fill right shift)
Logical	AND, OR, NOT
Comparison	=, !=, <, >, <=, >=, <>
String	|| (concatenate)

The following queries use binary operators:

```
SELECT *
FROM Families.children[0] c
WHERE c.grade % 2 = 1     -- matching grades == 5, 1

SELECT *
FROM Families.children[0] c
WHERE c.grade ^ 4 = 1    -- matching grades == 5

SELECT *
FROM Families.children[0] c
WHERE c.grade >= 5    -- matching grades == 5
```

You can also use the unary operators +,-, ~, and NOT in queries, as shown in the following examples:

```
SELECT *
FROM Families.children[0] c
WHERE NOT(c.grade = 5)  -- matching grades == 1

SELECT *
FROM Families.children[0] c
WHERE (-c.grade = -5)  -- matching grades == 5
```

You can also use property references in queries. For example, `SELECT * FROM Families f WHERE f.isRegistered` returns the JSON item containing the property `isRegistered` with value equal to `true`. Any other value, such as `false`, `null`, `Undefined`, `<number>`, `<string>`, `<object>`, or `<array>`, excludes the item from the result. Additionally, you can use the `IS_DEFINED` type checking function to query based on the presence or absence of a given JSON property. For instance, `SELECT * FROM Families f WHERE NOT IS_DEFINED(f.isRegistered)` returns any

JSON item that does not have a value for `isRegistered`.

- IN keyword
- FROM clause

ORDER BY clause in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

The optional `ORDER BY` clause specifies the sorting order for results returned by the query.

Syntax

```
ORDER BY <sort_specification>
<sort_specification> ::= <sort_expression> [, <sort_expression>]
<sort_expression> ::= {<scalar_expression> [ASC | DESC]} [ ,...n ]
```

Arguments

- `<sort_specification>`

  Specifies a property or expression on which to sort the query result set. A sort column can be specified as a name or property alias.

  Multiple properties can be specified. Property names must be unique. The sequence of the sort properties in the `ORDER BY` clause defines the organization of the sorted result set. That is, the result set is sorted by the first property and then that ordered list is sorted by the second property, and so on.

  The property names referenced in the `ORDER BY` clause must correspond to either a property in the select list or to a property defined in the collection specified in the `FROM` clause without any ambiguities.

- `<sort_expression>`

  Specifies one or more properties or expressions on which to sort the query result set.

- `<scalar_expression>`

  See the Scalar expressions section for details.

- `ASC | DESC`

  Specifies that the values in the specified column should be sorted in ascending or descending order. `ASC` sorts from the lowest value to highest value. `DESC` sorts from highest value to lowest value. `ASC` is the default sort order. Null values are treated as the lowest possible values.

Remarks

The `ORDER BY` clause requires that the indexing policy include an index for the fields being sorted. The Azure Cosmos DB query runtime supports sorting against a property name and not against computed properties. Azure Cosmos DB supports multiple `ORDER BY` properties. In order to run a query with multiple ORDER BY properties, you should define a composite index on the fields being sorted.

> **NOTE**
> If the properties being sorted might be undefined for some documents and you want to retrieve them in an ORDER BY query, you must explicitly include this path in the index. The default indexing policy won't allow for the retrieval of the documents where the sort property is undefined. Review example queries on documents with some missing fields.

Examples

For example, here's a query that retrieves families in ascending order of the resident city's name:

```
SELECT f.id, f.address.city
FROM Families f
ORDER BY f.address.city
```

The results are:

```
[
  {
    "id": "WakefieldFamily",
    "city": "NY"
  },
  {
    "id": "AndersenFamily",
    "city": "Seattle"
  }
]
```

The following query retrieves family `id`s in order of their item creation date. Item `creationDate` is a number representing the *epoch time*, or elapsed time since Jan. 1, 1970 in seconds.

```
SELECT f.id, f.creationDate
FROM Families f
ORDER BY f.creationDate DESC
```

The results are:

```
[
  {
    "id": "WakefieldFamily",
    "creationDate": 1431620462
  },
  {
    "id": "AndersenFamily",
    "creationDate": 1431620472
  }
]
```

Additionally, you can order by multiple properties. A query that orders by multiple properties requires a composite index. Consider the following query:

```
SELECT f.id, f.creationDate
FROM Families f
ORDER BY f.address.city ASC, f.creationDate DESC
```

This query retrieves the family `id` in ascending order of the city name. If multiple items have the same city name,

the query will order by the `creationDate` in descending order.

Documents with missing fields

Queries with `ORDER BY` that are run against containers with the default indexing policy will not return documents where the sort property is undefined. If you would like to include documents where the sort property is undefined, you should explicitly include this property in the indexing policy.

For example, here's a container with an indexing policy that does not explicitly include any paths besides `"/*"`:

```
{
    "indexingMode": "consistent",
    "automatic": true,
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "excludedPaths": []
}
```

If you run a query that includes `lastName` in the `Order By` clause, the results will only include documents that have a `lastName` property defined. We have not defined an explicit included path for `lastName` so any documents without a `lastName` will not appear in the query results.

Here is a query that sorts by `lastName` on two documents, one of which does not have a `lastName` defined:

```
SELECT f.id, f.lastName
FROM Families f
ORDER BY f.lastName
```

The results only include the document that has a defined `lastName`:

```
[
    {
        "id": "AndersenFamily",
        "lastName": "Andersen"
    }
]
```

If we update the container's indexing policy to explicitly include a path for `lastName`, we will include documents with an undefined sort property in the query results. You must explicitly define the path to lead to this scalar value (and not beyond it). You should use the `?` character in your path definition in the indexing policy to ensure that you explicitly index the property `lastName` and no additional nested paths beyond it. If your `Order By` query uses a composite index, the results will always include documents with an undefined sort property in the query results.

Here is a sample indexing policy which allows you to have documents with an undefined `lastName` appear in the query results:

```
{
    "indexingMode": "consistent",
    "automatic": true,
    "includedPaths": [
        {
            "path": "/lastName/?"
        },
        {
            "path": "/*"
        }
    ],
    "excludedPaths": []
}
```

If you run the same query again, documents that are missing `lastName` appear first in the query results:

```
    SELECT f.id, f.lastName
    FROM Families f
    ORDER BY f.lastName
```

The results are:

```
[
    {
        "id": "WakefieldFamily"
    },
    {
        "id": "AndersenFamily",
        "lastName": "Andersen"
    }
]
```

If you modify the sort order to `DESC`, documents that are missing `lastName` appear last in the query results:

```
    SELECT f.id, f.lastName
    FROM Families f
    ORDER BY f.lastName DESC
```

The results are:

```
[
    {
        "id": "AndersenFamily",
        "lastName": "Andersen"
    },
    {
        "id": "WakefieldFamily"
    }
]
```

NOTE

Only the .NET SDK version 3.4.0 or later supports ORDER BY with mixed types. Therefore, if you want to sort by a combination of undefined and defined values, you should use this version (or later).

You can't control the order that different types appear in the results. In the above example, we showed how undefined values were sorted before string values. If instead, for example, you wanted more control over the sort

order of undefined values, you could assign any undefined properties a string value of "aaaaaaaaa" or "zzzzzzzz" to ensure they were either first or last.

- OFFSET LIMIT clause

GROUP BY clause in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The GROUP BY clause divides the query's results according to the values of one or more specified properties.

Syntax

```
<group_by_clause> ::= GROUP BY <scalar_expression_list>

<scalar_expression_list> ::=
          <scalar_expression>
        | <scalar_expression_list>, <scalar_expression>
```

Arguments

- `<scalar_expression_list>`

  Specifies the expressions that will be used to divide query results.

- `<scalar_expression>`

  Any scalar expression is allowed except for scalar subqueries and scalar aggregates. Each scalar expression must contain at least one property reference. There is no limit to the number of individual expressions or the cardinality of each expression.

Remarks

When a query uses a GROUP BY clause, the SELECT clause can only contain the subset of properties and system functions included in the GROUP BY clause. One exception is aggregate functions, which can appear in the SELECT clause without being included in the GROUP BY clause. You can also always include literal values in the SELECT clause.

The GROUP BY clause must be after the SELECT, FROM, and WHERE clause and before the OFFSET LIMIT clause. You currently cannot use GROUP BY with an ORDER BY clause but this is planned.

The GROUP BY clause does not allow any of the following:

- Aliasing properties or aliasing system functions (aliasing is still allowed within the SELECT clause)
- Subqueries
- Aggregate system functions (these are only allowed in the SELECT clause)

Queries with an aggregate system function and a subquery with `GROUP BY` are not supported. For example, the following query is not supported:

```
SELECT COUNT(UniqueLastNames)
FROM (
SELECT AVG(f.age)
FROM f
GROUP BY f.lastName
) AS UniqueLastNames
```

Examples

These examples use the nutrition data set available through the Azure Cosmos DB Query Playground.

For example, here's a query which returns the total count of items in each foodGroup:

```
SELECT TOP 4 COUNT(1) AS foodGroupCount, f.foodGroup
FROM Food f
GROUP BY f.foodGroup
```

Some results are (TOP keyword is used to limit results):

```
[
    {
        "foodGroupCount": 183,
        "foodGroup": "Cereal Grains and Pasta"
    },
    {
        "foodGroupCount": 133,
        "foodGroup": "Nut and Seed Products"
    },
    {
        "foodGroupCount": 113,
        "foodGroup": "Meals, Entrees, and Side Dishes"
    },
    {
        "foodGroupCount": 64,
        "foodGroup": "Spices and Herbs"
    }
]
```

This query has two expressions used to divide results:

```
SELECT TOP 4 COUNT(1) AS foodGroupCount, f.foodGroup, f.version
FROM Food f
GROUP BY f.foodGroup, f.version
```

Some results are:

```
[
    {
        "foodGroupCount": 183,
        "foodGroup": "Cereal Grains and Pasta",
        "version": 1
    },
    {
        "foodGroupCount": 133,
        "foodGroup": "Nut and Seed Products",
        "version": 1
    },
    {
        "foodGroupCount": 113,
        "foodGroup": "Meals, Entrees, and Side Dishes",
        "version": 1
    },
    {
        "foodGroupCount": 64,
        "foodGroup": "Spices and Herbs",
        "version": 1
    }
]
```

This query has a system function in the GROUP BY clause:

```
SELECT TOP 4 COUNT(1) AS foodGroupCount, UPPER(f.foodGroup) AS upperFoodGroup
FROM Food f
GROUP BY UPPER(f.foodGroup)
```

Some results are:

```
[
    {
        "foodGroupCount": 183,
        "upperFoodGroup": "CEREAL GRAINS AND PASTA"
    },
    {
        "foodGroupCount": 133,
        "upperFoodGroup": "NUT AND SEED PRODUCTS"
    },
    {
        "foodGroupCount": 113,
        "upperFoodGroup": "MEALS, ENTREES, AND SIDE DISHES"
    },
    {
        "foodGroupCount": 64,
        "upperFoodGroup": "SPICES AND HERBS"
    }
]
```

This query uses both keywords and system functions in the item property expression:

```
SELECT COUNT(1) AS foodGroupCount, ARRAY_CONTAINS(f.tags, {name: 'orange'}) AS containsOrangeTag,  f.version
BETWEEN 0 AND 2 AS correctVersion
FROM Food f
GROUP BY ARRAY_CONTAINS(f.tags, {name: 'orange'}), f.version BETWEEN 0 AND 2
```

The results are:

```
[
    {
        "foodGroupCount": 10,
        "containsOrangeTag": true,
        "correctVersion": true
    },
    {
        "foodGroupCount": 8608,
        "containsOrangeTag": false,
        "correctVersion": true
    }
]
```

- SELECT clause
- Aggregate functions

OFFSET LIMIT clause in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The OFFSET LIMIT clause is an optional clause to skip then take some number of values from the query. The OFFSET count and the LIMIT count are required in the OFFSET LIMIT clause.

When OFFSET LIMIT is used in conjunction with an ORDER BY clause, the result set is produced by doing skip and take on the ordered values. If no ORDER BY clause is used, it will result in a deterministic order of values.

Syntax

```
OFFSET <offset_amount> LIMIT <limit_amount>
```

Arguments

- `<offset_amount>`

  Specifies the integer number of items that the query results should skip.

- `<limit_amount>`

  Specifies the integer number of items that the query results should include

Remarks

Both the `OFFSET` count and the `LIMIT` count are required in the `OFFSET LIMIT` clause. If an optional `ORDER BY` clause is used, the result set is produced by doing the skip over the ordered values. Otherwise, the query will return a fixed order of values.

The RU charge of a query with `OFFSET LIMIT` will increase as the number of terms being offset increases. For queries that have multiple pages of results, we typically recommend using continuation tokens. Continuation tokens are a "bookmark" for the place where the query can later resume. If you use `OFFSET LIMIT`, there is no "bookmark". If you wanted to return the query's next page, you would have to start from the beginning.

You should use `OFFSET LIMIT` for cases when you would like to skip items entirely and save client resources. For example, you should use `OFFSET LIMIT` if you want to skip to the 1000th query result and have no need to view results 1 through 999. On the backend, `OFFSET LIMIT` still loads each item, including those that are skipped. The performance advantage is a savings in client resources by avoiding processing items that are not needed.

Examples

For example, here's a query that skips the first value and returns the second value (in order of the resident city's name):

```
SELECT f.id, f.address.city
FROM Families f
ORDER BY f.address.city
OFFSET 1 LIMIT 1
```

The results are:

```
[
  {
    "id": "AndersenFamily",
    "city": "Seattle"
  }
]
```

Here's a query that skips the first value and returns the second value (without ordering):

```
SELECT f.id, f.address.city
FROM Families f
OFFSET 1 LIMIT 1
```

The results are:

```
[
  {
    "id": "WakefieldFamily",
    "city": "Seattle"
  }
]
```

Next steps

- SELECT clause
- ORDER BY clause

Working with JSON in Azure Cosmos DB

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

In Azure Cosmos DB's SQL (Core) API, items are stored as JSON. The type system and expressions are restricted to deal only with JSON types. For more information, see the JSON specification.

We'll summarize some important aspects of working with JSON:

- JSON objects always begin with a `{` left brace and end with a `}` right brace
- You can have JSON properties nested within one another
- JSON property values can be arrays
- JSON property names are case sensitive
- JSON property name can be any string value (including spaces or characters that aren't letters)

Nested properties

You can access nested JSON using a dot accessor. You can use nested JSON properties in your queries the same way that you can use any other properties.

Here's a document with nested JSON:

```
{
  "id": "AndersenFamily",
  "lastName": "Andersen",
  "address": {
      "state": "WA",
      "county": "King",
      "city": "Seattle"
      },
  "creationDate": 1431620472,
  "isRegistered": true
}
```

In this case, the `state`, `country`, and `city` properties are all nested within the `address` property.

The following example projects two nested properties: `f.address.state` and `f.address.city`.

```
SELECT f.address.state, f.address.city
FROM Families f
WHERE f.id = "AndersenFamily"
```

The results are:

```
[{
  "state": "WA",
  "city": "Seattle"
}]
```

Working with arrays

In addition to nested properties, JSON also supports arrays.

Here's an example document with an array:

```
{
  "id": "WakefieldFamily",
  "children": [
      {
        "familyName": "Merriam",
        "givenName": "Jesse",
        "gender": "female",
        "grade": 1,
      },
      {
        "familyName": "Miller",
         "givenName": "Lisa",
         "gender": "female",
         "grade": 8
      }
  ],
}
```

When working with arrays, you can access a specific element within the array by referencing its position:

```
SELECT *
FROM Families f
WHERE f.children[0].givenName = "Jesse"
```

In most cases, however, you'll use a subquery or self-join when working with arrays.

For example, here's a document that shows the daily balance of a customer's bank account.

```
{
  "id": "Contoso-Checking-Account-2020",
  "balance": [
      {
        "checkingAccount": 1000,
        "savingsAccount": 5000
      },
      {
        "checkingAccount": 100,
        "savingsAccount": 5000
      },
      {
        "checkingAccount": -10,
        "savingsAccount": 5000,
      },
      {
        "checkingAccount": 5000,
        "savingsAccount": 5000,
      }
         ...
  ]
}
```

If you wanted to run a query that showed all the customers that had a negative balance at some point, you could use EXISTS with a subquery:

```
SELECT c.id
FROM c
WHERE EXISTS(
    SELECT VALUE n
    FROM n IN c.balance
    WHERE n.checkingAccount < 0
)
```

Difference between null and undefined

If a property is not defined in an item, then its value is `undefined`. A property with the value `null` must be explicitly defined and assigned a `null` value.

For example, consider this sample item:

```
{
  "id": "AndersenFamily",
  "lastName": "Andersen",
  "address": {
      "state": "WA",
      "county": "King",
      "city": "Seattle"
      },
  "creationDate": null
}
```

In this example, the property `isRegistered` has a value of `undefined` because it is omitted from the item. The property `creationDate` has a `null` value.

Azure Cosmos DB supports two helpful type checking system functions for `null` and `undefined` properties:

- IS_NULL - checks if a property value is `null`
- IS_DEFINED - checks if a property value is defined

You can learn about supported operators and their behavior for `null` and `undefined` values.

Reserved keywords and special characters in JSON

You can access properties using the quoted property operator `[]`. For example, `SELECT c.grade` and `SELECT c["grade"]` are equivalent. This syntax is useful to escape a property that contains spaces, special characters, or has the same name as a SQL keyword or reserved word.

For example, here's a document with a property named `order` and a property `price($)` that contains special characters:

```
{
  "id": "AndersenFamily",
  "order": {
         "orderId": "12345",
         "productId": "A17849",
         "price($)": 59.33
   },
  "creationDate": 1431620472,
  "isRegistered": true
}
```

If you run a queries that includes the `order` property or `price($)` property, you will receive a syntax error.

```
SELECT * FROM c where c.order.orderid = "12345"
```

```
SELECT * FROM c where c.order.price($) > 50
```

The result is:

`Syntax error, incorrect syntax near 'order'`

You should rewrite the same queries as below:

```
SELECT * FROM c WHERE c["order"].orderId = "12345"
```

```
SELECT * FROM c WHERE c["order"]["price($)"] > 50
```

JSON expressions

Projection also supports JSON expressions, as shown in the following example:

```
    SELECT { "state": f.address.state, "city": f.address.city, "name": f.id }
    FROM Families f
    WHERE f.id = "AndersenFamily"
```

The results are:

```
    [{
      "$1": {
        "state": "WA",
        "city": "Seattle",
        "name": "AndersenFamily"
      }
    }]
```

In the preceding example, the `SELECT` clause needs to create a JSON object, and since the sample provides no key, the clause uses the implicit argument variable name `$1`. The following query returns two implicit argument variables: `$1` and `$2`.

```
    SELECT { "state": f.address.state, "city": f.address.city },
           { "name": f.id }
    FROM Families f
    WHERE f.id = "AndersenFamily"
```

The results are:

```
    [{
      "$1": {
        "state": "WA",
        "city": "Seattle"
      },
      "$2": {
        "name": "AndersenFamily"
      }
    }]
```

Aliasing

You can explicitly alias values in queries. If a query has two properties with the same name, use aliasing to rename one or both of the properties so they're disambiguated in the projected result.

Examples

The `AS` keyword used for aliasing is optional, as shown in the following example when projecting the second value as `NameInfo`:

```
SELECT
       { "state": f.address.state, "city": f.address.city } AS AddressInfo,
       { "name": f.id } NameInfo
FROM Families f
WHERE f.id = "AndersenFamily"
```

The results are:

```
[{
  "AddressInfo": {
    "state": "WA",
    "city": "Seattle"
  },
  "NameInfo": {
    "name": "AndersenFamily"
  }
}]
```

Aliasing with reserved keywords or special characters

You can't use aliasing to project a value as a property name with a space, special character, or reserved word. If you wanted to change a value's projection to, for example, have a property name with a space, you could use a JSON expression.

Here's an example:

```
SELECT
       {"JSON expression with a space": { "state": f.address.state, "city": f.address.city }},
       {"JSON expression with a special character!": { "name": f.id }}
FROM Families f
WHERE f.id = "AndersenFamily"
```

SQL subquery examples for Azure Cosmos DB

12/4/2020 • 12 minutes to read • Edit Online

APPLIES TO: SQL API

A subquery is a query nested within another query. A subquery is also called an inner query or inner select. The statement that contains a subquery is typically called an outer query.

This article describes SQL subqueries and their common use cases in Azure Cosmos DB. All sample queries in this doc can be run against a nutrition dataset that is preloaded on the Azure Cosmos DB Query Playground.

Types of subqueries

There are two main types of subqueries:

- **Correlated**: A subquery that references values from the outer query. The subquery is evaluated once for each row that the outer query processes.
- **Non-correlated**: A subquery that's independent of the outer query. It can be run on its own without relying on the outer query.

> **NOTE**
> Azure Cosmos DB supports only correlated subqueries.

Subqueries can be further classified based on the number of rows and columns that they return. There are three types:

- **Table**: Returns multiple rows and multiple columns.
- **Multi-value**: Returns multiple rows and a single column.
- **Scalar**: Returns a single row and a single column.

SQL queries in Azure Cosmos DB always return a single column (either a simple value or a complex document). Therefore, only multi-value and scalar subqueries are applicable in Azure Cosmos DB. You can use a multi-value subquery only in the FROM clause as a relational expression. You can use a scalar subquery as a scalar expression in the SELECT or WHERE clause, or as a relational expression in the FROM clause.

Multi-value subqueries

Multi-value subqueries return a set of documents and are always used within the FROM clause. They're used for:

- Optimizing JOIN expressions.
- Evaluating expensive expressions once and referencing multiple times.

Optimize JOIN expressions

Multi-value subqueries can optimize JOIN expressions by pushing predicates after each select-many expression rather than after all cross-joins in the WHERE clause.

Consider the following query:

```
SELECT Count(1) AS Count
FROM c
JOIN t IN c.tags
JOIN n IN c.nutrients
JOIN s IN c.servings
WHERE t.name = 'infant formula' AND (n.nutritionValue > 0
AND n.nutritionValue < 10) AND s.amount > 1
```

For this query, the index will match any document that has a tag with the name "infant formula." It's a nutrient item with a value between 0 and 10, and a serving item with an amount greater than 1. The JOIN expression here will perform the cross-product of all items of tags, nutrients, and servings arrays for each matching document before any filter is applied.

The WHERE clause will then apply the filter predicate on each <c, t, n, s> tuple. For instance, if a matching document had 10 items in each of the three arrays, it will expand to 1 x 10 x 10 x 10 (that is, 1,000) tuples. Using subqueries here can help in filtering out joined array items before joining with the next expression.

This query is equivalent to the preceding one but uses subqueries:

```
SELECT Count(1) AS Count
FROM c
JOIN (SELECT VALUE t FROM t IN c.tags WHERE t.name = 'infant formula')
JOIN (SELECT VALUE n FROM n IN c.nutrients WHERE n.nutritionValue > 0 AND n.nutritionValue < 10)
JOIN (SELECT VALUE s FROM s IN c.servings WHERE s.amount > 1)
```

Assume that only one item in the tags array matches the filter, and there are five items for both nutrients and servings arrays. The JOIN expressions will then expand to 1 x 1 x 5 x 5 = 25 items, as opposed to 1,000 items in the first query.

Evaluate once and reference many times

Subqueries can help optimize queries with expensive expressions such as user-defined functions (UDFs), complex strings, or arithmetic expressions. You can use a subquery along with a JOIN expression to evaluate the expression once but reference it many times.

The following query runs the UDF `GetMaxNutritionValue` twice:

```
SELECT c.id, udf.GetMaxNutritionValue(c.nutrients) AS MaxNutritionValue
FROM c
WHERE udf.GetMaxNutritionValue(c.nutrients) > 100
```

Here's an equivalent query that runs the UDF only once:

```
SELECT TOP 1000 c.id, MaxNutritionValue
FROM c
JOIN (SELECT VALUE udf.GetMaxNutritionValue(c.nutrients)) MaxNutritionValue
WHERE MaxNutritionValue > 100
```

> **NOTE**
>
> Keep in mind the cross-product behavior of JOIN expressions. If the UDF expression can evaluate to undefined, you should ensure that the JOIN expression always produces a single row by returning an object from the subquery rather than the value directly.

Here's a similar example that returns an object rather than a value:

```
SELECT TOP 1000 c.id, m.MaxNutritionValue
FROM c
JOIN (SELECT udf.GetMaxNutritionValue(c.nutrients) AS MaxNutritionValue) m
WHERE m.MaxNutritionValue > 100
```

The approach is not limited to UDFs. It applies to any potentially expensive expression. For example, you can take the same approach with the mathematical function `avg`:

```
SELECT TOP 1000 c.id, AvgNutritionValue
FROM c
JOIN (SELECT VALUE avg(n.nutritionValue) FROM n IN c.nutrients) AvgNutritionValue
WHERE AvgNutritionValue > 80
```

Mimic join with external reference data

You might often need to reference static data that rarely changes, such as units of measurement or country codes. It's better not to duplicate such data for each document. Avoiding this duplication will save on storage and improve write performance by keeping the document size smaller. You can use a subquery to mimic inner-join semantics with a collection of reference data.

For instance, consider this set of reference data:

UNIT	NAME	MULTIPLIER	BASE UNIT
ng	Nanogram	1.00E-09	Gram
µg	Microgram	1.00E-06	Gram
mg	Milligram	1.00E-03	Gram
g	Gram	1.00E+00	Gram
kg	Kilogram	1.00E+03	Gram
Mg	Megagram	1.00E+06	Gram
Gg	Gigagram	1.00E+09	Gram
nJ	Nanojoule	1.00E-09	Joule
µJ	Microjoule	1.00E-06	Joule
mJ	Millijoule	1.00E-03	Joule
J	Joule	1.00E+00	Joule
kJ	Kilojoule	1.00E+03	Joule
MJ	Megajoule	1.00E+06	Joule
GJ	Gigajoule	1.00E+09	Joule

UNIT	NAME	MULTIPLIER	BASE UNIT
cal	Calorie	1.00E+00	calorie
kcal	Calorie	1.00E+03	calorie
IU	International units		

The following query mimics joining with this data so that you add the name of the unit to the output:

```
SELECT TOP 10 n.id, n.description, n.nutritionValue, n.units, r.name
FROM food
JOIN n IN food.nutrients
JOIN r IN (
    SELECT VALUE [
        {unit: 'ng', name: 'nanogram', multiplier: 0.000000001, baseUnit: 'gram'},
        {unit: 'µg', name: 'microgram', multiplier: 0.000001, baseUnit: 'gram'},
        {unit: 'mg', name: 'milligram', multiplier: 0.001, baseUnit: 'gram'},
        {unit: 'g', name: 'gram', multiplier: 1, baseUnit: 'gram'},
        {unit: 'kg', name: 'kilogram', multiplier: 1000, baseUnit: 'gram'},
        {unit: 'Mg', name: 'megagram', multiplier: 1000000, baseUnit: 'gram'},
        {unit: 'Gg', name: 'gigagram', multiplier: 1000000000, baseUnit: 'gram'},
        {unit: 'nJ', name: 'nanojoule', multiplier: 0.000000001, baseUnit: 'joule'},
        {unit: 'µJ', name: 'microjoule', multiplier: 0.000001, baseUnit: 'joule'},
        {unit: 'mJ', name: 'millijoule', multiplier: 0.001, baseUnit: 'joule'},
        {unit: 'J', name: 'joule', multiplier: 1, baseUnit: 'joule'},
        {unit: 'kJ', name: 'kilojoule', multiplier: 1000, baseUnit: 'joule'},
        {unit: 'MJ', name: 'megajoule', multiplier: 1000000, baseUnit: 'joule'},
        {unit: 'GJ', name: 'gigajoule', multiplier: 1000000000, baseUnit: 'joule'},
        {unit: 'cal', name: 'calorie', multiplier: 1, baseUnit: 'calorie'},
        {unit: 'kcal', name: 'Calorie', multiplier: 1000, baseUnit: 'calorie'},
        {unit: 'IU', name: 'International units'}
    ]
)
WHERE n.units = r.unit
```

Scalar subqueries

A scalar subquery expression is a subquery that evaluates to a single value. The value of the scalar subquery expression is the value of the projection (SELECT clause) of the subquery. You can use a scalar subquery expression in many places where a scalar expression is valid. For instance, you can use a scalar subquery in any expression in both the SELECT and WHERE clauses.

Using a scalar subquery doesn't always help optimize, though. For example, passing a scalar subquery as an argument to either a system or user-defined functions provides no benefit in resource unit (RU) consumption or latency.

Scalar subqueries can be further classified as:

- Simple-expression scalar subqueries
- Aggregate scalar subqueries

Simple-expression scalar subqueries

A simple-expression scalar subquery is a correlated subquery that has a SELECT clause that doesn't contain any aggregate expressions. These subqueries provide no optimization benefits because the compiler converts them into one larger simple expression. There's no correlated context between the inner and outer queries.

Here are few examples:

Example 1

```
SELECT 1 AS a, 2 AS b
```

You can rewrite this query, by using a simple-expression scalar subquery, to:

```
SELECT (SELECT VALUE 1) AS a, (SELECT VALUE 2) AS b
```

Both queries produce this output:

```
[
  { "a": 1, "b": 2 }
]
```

Example 2

```
SELECT TOP 5 Concat('id_', f.id) AS id
FROM food f
```

You can rewrite this query, by using a simple-expression scalar subquery, to:

```
SELECT TOP 5 (SELECT VALUE Concat('id_', f.id)) AS id
FROM food f
```

Query output:

```
[
  { "id": "id_03226" },
  { "id": "id_03227" },
  { "id": "id_03228" },
  { "id": "id_03229" },
  { "id": "id_03230" }
]
```

Example 3

```
SELECT TOP 5 f.id, Contains(f.description, 'fruit') = true ? f.description : undefined
FROM food f
```

You can rewrite this query, by using a simple-expression scalar subquery, to:

```
SELECT TOP 10 f.id, (SELECT f.description WHERE Contains(f.description, 'fruit')).description
FROM food f
```

Query output:

```
[
  { "id": "03230" },
  { "id": "03238", "description":"Babyfood, dessert, tropical fruit, junior" },
  { "id": "03229" },
  { "id": "03226", "description":"Babyfood, dessert, fruit pudding, orange, strained" },
  { "id": "03227" }
]
```

Aggregate scalar subqueries

An aggregate scalar subquery is a subquery that has an aggregate function in its projection or filter that evaluates to a single value.

Example 1:

Here's a subquery with a single aggregate function expression in its projection:

```
SELECT TOP 5
    f.id,
    (SELECT VALUE Count(1) FROM n IN f.nutrients WHERE n.units = 'mg'
) AS count_mg
FROM food f
```

Query output:

```
[
  { "id": "03230", "count_mg": 13 },
  { "id": "03238", "count_mg": 14 },
  { "id": "03229", "count_mg": 13 },
  { "id": "03226", "count_mg": 15 },
  { "id": "03227", "count_mg": 19 }
]
```

Example 2

Here's a subquery with multiple aggregate function expressions:

```
SELECT TOP 5 f.id, (
    SELECT Count(1) AS count, Sum(n.nutritionValue) AS sum
    FROM n IN f.nutrients
    WHERE n.units = 'mg'
) AS unit_mg
FROM food f
```

Query output:

```
[
  { "id": "03230","unit_mg": { "count": 13,"sum": 147.072 } },
  { "id": "03238","unit_mg": { "count": 14,"sum": 107.385 } },
  { "id": "03229","unit_mg": { "count": 13,"sum": 141.579 } },
  { "id": "03226","unit_mg": { "count": 15,"sum": 183.91399999999996 } },
  { "id": "03227","unit_mg": { "count": 19,"sum": 94.788999999999987 } }
]
```

Example 3

Here's a query with an aggregate subquery in both the projection and the filter:

```
SELECT TOP 5
    f.id,
 (SELECT VALUE Count(1) FROM n IN f.nutrients WHERE n.units = 'mg') AS count_mg
FROM food f
WHERE (SELECT VALUE Count(1) FROM n IN f.nutrients WHERE n.units = 'mg') > 20
```

Query output:

```
[
  { "id": "03235", "count_mg": 27 },
  { "id": "03246", "count_mg": 21 },
  { "id": "03267", "count_mg": 21 },
  { "id": "03269", "count_mg": 21 },
  { "id": "03274", "count_mg": 21 }
]
```

A more optimal way to write this query is to join on the subquery and reference the subquery alias in both the SELECT and WHERE clauses. This query is more efficient because you need to execute the subquery only within the join statement, and not in both the projection and filter.

```
SELECT TOP 5 f.id, count_mg
FROM food f
JOIN (SELECT VALUE Count(1) FROM n IN f.nutrients WHERE n.units = 'mg') AS count_mg
WHERE count_mg > 20
```

EXISTS expression

Azure Cosmos DB supports EXISTS expressions. This is an aggregate scalar subquery built into the Azure Cosmos DB SQL API. EXISTS is a Boolean expression that takes a subquery expression and returns true if the subquery returns any rows. Otherwise, it returns false.

Because the Azure Cosmos DB SQL API doesn't differentiate between Boolean expressions and any other scalar expressions, you can use EXISTS in both SELECT and WHERE clauses. This is unlike T-SQL, where a Boolean expression (for example, EXISTS, BETWEEN, and IN) is restricted to the filter.

If the EXISTS subquery returns a single value that's undefined, EXISTS will evaluate to false. For instance, consider the following query that evaluates to false:

```
SELECT EXISTS (SELECT VALUE undefined)
```

If the VALUE keyword in the preceding subquery is omitted, the query will evaluate to true:

```
SELECT EXISTS (SELECT undefined)
```

The subquery will enclose the list of values in the selected list in an object. If the selected list has no values, the subquery will return the single value '{}'. This value is defined, so EXISTS evaluates to true.

Example: Rewriting ARRAY_CONTAINS and JOIN as EXISTS

A common use case of ARRAY_CONTAINS is to filter a document by the existence of an item in an array. In this case, we're checking to see if the tags array contains an item named "orange."

```
SELECT TOP 5 f.id, f.tags
FROM food f
WHERE ARRAY_CONTAINS(f.tags, {name: 'orange'})
```

You can rewrite the same query to use EXISTS:

```
SELECT TOP 5 f.id, f.tags
FROM food f
WHERE EXISTS(SELECT VALUE t FROM t IN f.tags WHERE t.name = 'orange')
```

Additionally, ARRAY_CONTAINS can only check if a value is equal to any element within an array. If you need more complex filters on array properties, use JOIN.

Consider the following query that filters based on the units and `nutritionValue` properties in the array:

```
SELECT VALUE c.description
FROM c
JOIN n IN c.nutrients
WHERE n.units= "mg" AND n.nutritionValue > 0
```

For each of the documents in the collection, a cross-product is performed with its array elements. This JOIN operation makes it possible to filter on properties within the array. However, this query's RU consumption will be significant. For instance, if 1,000 documents had 100 items in each array, it will expand to 1,000 x 100 (that is, 100,000) tuples.

Using EXISTS can help to avoid this expensive cross-product:

```
SELECT VALUE c.description
FROM c
WHERE EXISTS(
    SELECT VALUE n
    FROM n IN c.nutrients
    WHERE n.units = "mg" AND n.nutritionValue > 0
)
```

In this case, you filter on array elements within the EXISTS subquery. If an array element matches the filter, then you project it and EXISTS evaluates to true.

You can also alias EXISTS and reference it in the projection:

```
SELECT TOP 1 c.description, EXISTS(
    SELECT VALUE n
    FROM n IN c.nutrients
    WHERE n.units = "mg" AND n.nutritionValue > 0) as a
FROM c
```

Query output:

```
[
    {
        "description": "Babyfood, dessert, fruit pudding, orange, strained",
        "a": true
    }
]
```

ARRAY expression

You can use the ARRAY expression to project the results of a query as an array. You can use this expression only within the SELECT clause of the query.

```
SELECT TOP 1   f.id, ARRAY(SELECT VALUE t.name FROM t in f.tags) AS tagNames
FROM  food f
```

Query output:

```
[
    {
        "id": "03238",
        "tagNames": [
            "babyfood",
            "dessert",
            "tropical fruit",
            "junior"
        ]
    }
]
```

As with other subqueries, filters with the ARRAY expression are possible.

```
SELECT TOP 1 c.id, ARRAY(SELECT VALUE t FROM t in c.tags WHERE t.name != 'infant formula') AS tagNames
FROM c
```

Query output:

```
[
    {
        "id": "03226",
        "tagNames": [
            {
                "name": "babyfood"
            },
            {
                "name": "dessert"
            },
            {
                "name": "fruit pudding"
            },
            {
                "name": "orange"
            },
            {
                "name": "strained"
            }
        ]
    }
]
```

Array expressions can also come after the FROM clause in subqueries.

```
SELECT TOP 1 c.id, ARRAY(SELECT VALUE t.name FROM t in c.tags) as tagNames
FROM c
JOIN n IN (SELECT VALUE ARRAY(SELECT t FROM t in c.tags WHERE t.name != 'infant formula'))
```

Query output:

```
[
    {
        "id": "03238",
        "tagNames": [
            "babyfood",
            "dessert",
            "tropical fruit",
            "junior"
        ]
    }
]
```

Joins in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

In a relational database, joins across tables are the logical corollary to designing normalized schemas. In contrast, the SQL API uses the denormalized data model of schema-free items, which is the logical equivalent of a *self-join*.

Inner joins result in a complete cross product of the sets participating in the join. The result of an N-way join is a set of N-element tuples, where each value in the tuple is associated with the aliased set participating in the join and can be accessed by referencing that alias in other clauses.

Syntax

The language supports the syntax `<from_source1> JOIN <from_source2> JOIN ... JOIN <from_sourceN>`. This query returns a set of tuples with `N` values. Each tuple has values produced by iterating all container aliases over their respective sets.

Let's look at the following FROM clause: `<from_source1> JOIN <from_source2> JOIN ... JOIN <from_sourceN>`

Let each source define `input_alias1, input_alias2, …, input_aliasN`. This FROM clause returns a set of N-tuples (tuple with N values). Each tuple has values produced by iterating all container aliases over their respective sets.

Example 1 - 2 sources

- Let `<from_source1>` be container-scoped and represent set {A, B, C}.
- Let `<from_source2>` be document-scoped referencing input_alias1 and represent sets:

  {1, 2} for `input_alias1 = A,`

  {3} for `input_alias1 = B,`

  {4, 5} for `input_alias1 = C,`
- The FROM clause `<from_source1> JOIN <from_source2>` will result in the following tuples:

  (`input_alias1, input_alias2`):

  `(A, 1), (A, 2), (B, 3), (C, 4), (C, 5)`

Example 2 - 3 sources

- Let `<from_source1>` be container-scoped and represent set {A, B, C}.
- Let `<from_source2>` be document-scoped referencing `input_alias1` and represent sets:

  {1, 2} for `input_alias1 = A,`

  {3} for `input_alias1 = B,`

  {4, 5} for `input_alias1 = C,`
- Let `<from_source3>` be document-scoped referencing `input_alias2` and represent sets:

  {100, 200} for `input_alias2 = 1,`

{300} for `input_alias2 = 3,`

- The FROM clause `<from_source1> JOIN <from_source2> JOIN <from_source3>` will result in the following tuples:

  (input_alias1, input_alias2, input_alias3):

  (A, 1, 100), (A, 1, 200), (B, 3, 300)

> **NOTE**
> Lack of tuples for other values of `input_alias1`, `input_alias2`, for which the `<from_source3>` did not return any values.

Example 3 - 3 sources

- Let <from_source1> be container-scoped and represent set {A, B, C}.
- Let `<from_source1>` be container-scoped and represent set {A, B, C}.
- Let <from_source2> be document-scoped referencing input_alias1 and represent sets:

  {1, 2} for `input_alias1 = A,`

  {3} for `input_alias1 = B,`

  {4, 5} for `input_alias1 = C,`

- Let `<from_source3>` be scoped to `input_alias1` and represent sets:

  {100, 200} for `input_alias2 = A,`

  {300} for `input_alias2 = C,`

- The FROM clause `<from_source1> JOIN <from_source2> JOIN <from_source3>` will result in the following tuples:

  (`input_alias1, input_alias2, input_alias3`):

  (A, 1, 100), (A, 1, 200), (A, 2, 100), (A, 2, 200), (C, 4, 300) , (C, 5, 300)

> **NOTE**
> This resulted in cross product between `<from_source2>` and `<from_source3>` because both are scoped to the same `<from_source1>`. This resulted in 4 (2x2) tuples having value A, 0 tuples having value B (1x0) and 2 (2x1) tuples having value C.

Examples

The following examples show how the JOIN clause works. Before you run these examples, upload the sample family data. In the following example, the result is empty, since the cross product of each item from source and an empty set is empty:

```
SELECT f.id
FROM Families f
JOIN f.NonExistent
```

The result is:

```
[{
}]
```

In the following example, the join is a cross product between two JSON objects, the item root `id` and the `children` subroot. The fact that `children` is an array isn't effective in the join, because it deals with a single root that is the `children` array. The result contains only two results, because the cross product of each item with the array yields exactly only one item.

```
SELECT f.id
FROM Families f
JOIN f.children
```

The results are:

```
[
  {
    "id": "AndersenFamily"
  },
  {
    "id": "WakefieldFamily"
  }
]
```

The following example shows a more conventional join:

```
SELECT f.id
FROM Families f
JOIN c IN f.children
```

The results are:

```
[
  {
    "id": "AndersenFamily"
  },
  {
    "id": "WakefieldFamily"
  },
  {
    "id": "WakefieldFamily"
  }
]
```

The FROM source of the JOIN clause is an iterator. So, the flow in the preceding example is:

1. Expand each child element `c` in the array.
2. Apply a cross product with the root of the item `f` with each child element `c` that the first step flattened.
3. Finally, project the root object `f` `id` property alone.

The first item, `AndersenFamily`, contains only one `children` element, so the result set contains only a single object. The second item, `WakefieldFamily`, contains two `children`, so the cross product produces two objects, one for each `children` element. The root fields in both these items are the same, just as you would expect in a cross product.

The real utility of the JOIN clause is to form tuples from the cross product in a shape that's otherwise difficult to

project. The example below filters on the combination of a tuple that lets the user choose a condition satisfied by the tuples overall.

```
SELECT
    f.id AS familyName,
    c.givenName AS childGivenName,
    c.firstName AS childFirstName,
    p.givenName AS petName
FROM Families f
JOIN c IN f.children
JOIN p IN c.pets
```

The results are:

```
[
  {
    "familyName": "AndersenFamily",
    "childFirstName": "Henriette Thaulow",
    "petName": "Fluffy"
  },
  {
    "familyName": "WakefieldFamily",
    "childGivenName": "Jesse",
    "petName": "Goofy"
  },
  {
   "familyName": "WakefieldFamily",
   "childGivenName": "Jesse",
   "petName": "Shadow"
  }
]
```

The following extension of the preceding example performs a double join. You could view the cross product as the following pseudo-code:

```
for-each(Family f in Families)
{
    for-each(Child c in f.children)
    {
        for-each(Pet p in c.pets)
        {
            return (Tuple(f.id AS familyName,
              c.givenName AS childGivenName,
              c.firstName AS childFirstName,
              p.givenName AS petName));
        }
    }
}
```

`AndersenFamily` has one child who has one pet, so the cross product yields one row (1*1*1) from this family. `WakefieldFamily` has two children, only one of whom has pets, but that child has two pets. The cross product for this family yields 1*1*2 = 2 rows.

In the next example, there is an additional filter on `pet`, which excludes all the tuples where the pet name is not `Shadow`. You can build tuples from arrays, filter on any of the elements of the tuple, and project any combination of the elements.

```
SELECT
    f.id AS familyName,
    c.givenName AS childGivenName,
    c.firstName AS childFirstName,
    p.givenName AS petName
FROM Families f
JOIN c IN f.children
JOIN p IN c.pets
WHERE p.givenName = "Shadow"
```

The results are:

```
[
  {
   "familyName": "WakefieldFamily",
   "childGivenName": "Jesse",
   "petName": "Shadow"
  }
]
```

Working with arrays and objects in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

A key feature of the Azure Cosmos DB SQL API is array and object creation.

Arrays

You can construct arrays, as shown in the following example:

```
SELECT [f.address.city, f.address.state] AS CityState
FROM Families f
```

The results are:

```
[
  {
    "CityState": [
      "Seattle",
      "WA"
    ]
  },
  {
    "CityState": [
      "NY",
      "NY"
    ]
  }
]
```

You can also use the ARRAY expression to construct an array from subquery's results. This query gets all the distinct given names of children in an array.

```
SELECT f.id, ARRAY(SELECT DISTINCT VALUE c.givenName FROM c IN f.children) as ChildNames
FROM f
```

Iteration

The SQL API provides support for iterating over JSON arrays, with a new construct added via the IN keyword in the FROM source. In the following example:

```
SELECT *
FROM Families.children
```

The results are:

```
[
  [
    {
      "firstName": "Henriette Thaulow",
      "gender": "female",
      "grade": 5,
      "pets": [{ "givenName": "Fluffy"}]
    }
  ],
  [
    {
        "familyName": "Merriam",
        "givenName": "Jesse",
        "gender": "female",
        "grade": 1
    },
    {
        "familyName": "Miller",
        "givenName": "Lisa",
        "gender": "female",
        "grade": 8
    }
  ]
]
```

The next query performs iteration over `children` in the `Families` container. The output array is different from the preceding query. This example splits `children`, and flattens the results into a single array:

```
SELECT *
FROM c IN Families.children
```

The results are:

```
[
  {
      "firstName": "Henriette Thaulow",
      "gender": "female",
      "grade": 5,
      "pets": [{ "givenName": "Fluffy" }]
  },
  {
      "familyName": "Merriam",
      "givenName": "Jesse",
      "gender": "female",
      "grade": 1
  },
  {
      "familyName": "Miller",
      "givenName": "Lisa",
      "gender": "female",
      "grade": 8
  }
]
```

You can filter further on each individual entry of the array, as shown in the following example:

```
SELECT c.givenName
FROM c IN Families.children
WHERE c.grade = 8
```

The results are:

```
[{
  "givenName": "Lisa"
}]
```

You can also aggregate over the result of an array iteration. For example, the following query counts the number of children among all families:

```
SELECT COUNT(child)
FROM child IN Families.children
```

The results are:

```
[
  {
    "$1": 3
  }
]
```

- Joins

Keywords in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article details keywords which may be used in Azure Cosmos DB SQL queries.

BETWEEN

You can use the `BETWEEN` keyword to express queries against ranges of string or numerical values. For example, the following query returns all items in which the first child's grade is 1-5, inclusive.

```
SELECT *
FROM Families.children[0] c
WHERE c.grade BETWEEN 1 AND 5
```

You can also use the `BETWEEN` keyword in the `SELECT` clause, as in the following example.

```
SELECT (c.grade BETWEEN 0 AND 10)
FROM Families.children[0] c
```

In SQL API, unlike ANSI SQL, you can express range queries against properties of mixed types. For example, `grade` might be a number like `5` in some items and a string like `grade4` in others. In these cases, as in JavaScript, the comparison between the two different types results in `Undefined`, so the item is skipped.

DISTINCT

The `DISTINCT` keyword eliminates duplicates in the query's projection.

In this example, the query projects values for each last name:

```
SELECT DISTINCT VALUE f.lastName
FROM Families f
```

The results are:

```
[
    "Andersen"
]
```

You can also project unique objects. In this case, the lastName field does not exist in one of the two documents, so the query returns an empty object.

```
SELECT DISTINCT f.lastName
FROM Families f
```

The results are:

```
[
    {
        "lastName": "Andersen"
    },
    {}
]
```

`DISTINCT` can also be used in the projection within a subquery:

```
SELECT f.id, ARRAY(SELECT DISTINCT VALUE c.givenName FROM c IN f.children) as ChildNames
FROM f
```

This query projects an array which contains each child's givenName with duplicates removed. This array is aliased as ChildNames and projected in the outer query.

The results are:

```
[
    {
        "id": "AndersenFamily",
        "ChildNames": []
    },
    {
        "id": "WakefieldFamily",
        "ChildNames": [
            "Jesse",
            "Lisa"
        ]
    }
]
```

Queries with an aggregate system function and a subquery with `DISTINCT` are not supported. For example, the following query is not supported:

```
SELECT COUNT(1) FROM (SELECT DISTINCT f.lastName FROM f)
```

IN

Use the IN keyword to check whether a specified value matches any value in a list. For example, the following query returns all family items where the `id` is `WakefieldFamily` or `AndersenFamily`.

```
    SELECT *
    FROM Families
    WHERE Families.id IN ('AndersenFamily', 'WakefieldFamily')
```

The following example returns all items where the state is any of the specified values:

```
    SELECT *
    FROM Families
    WHERE Families.address.state IN ("NY", "WA", "CA", "PA", "OH", "OR", "MI", "WI", "MN", "FL")
```

The SQL API provides support for iterating over JSON arrays, with a new construct added via the in keyword in the FROM source.

If you include your partition key in the `IN` filter, your query will automatically filter to only the relevant partitions.

TOP

The TOP keyword returns the first `N` number of query results in an undefined order. As a best practice, use TOP with the `ORDER BY` clause to limit results to the first `N` number of ordered values. Combining these two clauses is the only way to predictably indicate which rows TOP affects.

You can use TOP with a constant value, as in the following example, or with a variable value using parameterized queries.

```
SELECT TOP 1 *
FROM Families f
```

The results are:

```
[{
    "id": "AndersenFamily",
    "lastName": "Andersen",
    "parents": [
       { "firstName": "Thomas" },
       { "firstName": "Mary Kay"}
    ],
    "children": [
       {
           "firstName": "Henriette Thaulow", "gender": "female", "grade": 5,
           "pets": [{ "givenName": "Fluffy" }]
       }
    ],
    "address": { "state": "WA", "county": "King", "city": "Seattle" },
    "creationDate": 1431620472,
    "isRegistered": true
}]
```

Azure Cosmos DB SQL query constants

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

A constant, also known as a literal or a scalar value, is a symbol that represents a specific data value. The format of a constant depends on the data type of the value it represents.

Supported scalar data types:

TYPE	VALUES ORDER
Undefined	Single value: **undefined**
Null	Single value: **null**
Boolean	Values: **false**, **true**.
Number	A double-precision floating-point number, IEEE 754 standard.
String	A sequence of zero or more Unicode characters. Strings must be enclosed in single or double quotes.
Array	A sequence of zero or more elements. Each element can be a value of any scalar data type, except **Undefined**.
Object	An unordered set of zero or more name/value pairs. Name is a Unicode string, value can be of any scalar data type, except **Undefined**.

Syntax

```
<constant> ::=
   <undefined_constant>
     | <null_constant>
     | <boolean_constant>
     | <number_constant>
     | <string_constant>
     | <array_constant>
     | <object_constant>

<undefined_constant> ::= undefined

<null_constant> ::= null

<boolean_constant> ::= false | true

<number_constant> ::= decimal_literal | hexadecimal_literal

<string_constant> ::= string_literal

<array_constant> ::=
    '[' [<constant>][,...n] ']'

<object_constant> ::=
   '{' [{property_name | "property_name"} : <constant>][,...n] '}'
```

Arguments

- `<undefined_constant>; Undefined`

  Represents undefined value of type Undefined.

- `<null_constant>; null`

  Represents **null** value of type **Null**.

- `<boolean_constant>`

  Represents constant of type Boolean.

- `false`

  Represents **false** value of type Boolean.

- `true`

  Represents **true** value of type Boolean.

- `<number_constant>`

  Represents a constant.

- `decimal_literal`

  Decimal literals are numbers represented using either decimal notation, or scientific notation.

- `hexadecimal_literal`

  Hexadecimal literals are numbers represented using prefix '0x' followed by one or more hexadecimal digits.

- `<string_constant>`

  Represents a constant of type String.

- `string _literal`

  String literals are Unicode strings represented by a sequence of zero or more Unicode characters or escape sequences. String literals are enclosed in single quotes (apostrophe: ') or double quotes (quotation mark: ").

  Following escape sequences are allowed:

ESCAPE SEQUENCE	DESCRIPTION	UNICODE CHARACTER
\'	apostrophe (')	U+0027
\"	quotation mark (")	U+0022
\\	reverse solidus (\)	U+005C
\/	solidus (/)	U+002F
\b	backspace	U+0008
\f	form feed	U+000C
\n	line feed	U+000A
\r	carriage return	U+000D
\t	tab	U+0009
\uXXXX	A Unicode character defined by 4 hexadecimal digits.	U+XXXX

Operators in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article details the various operators supported by Azure Cosmos DB.

Equality and Comparison Operators

The following table shows the result of equality comparisons in the SQL API between any two JSON types.

OP	UNDEFINED	NULL	BOOLEAN	NUMBER	STRING	OBJECT	ARRAY
Undefined	Undefined	Undefined	Undefined	Undefined	Undefined	Undefined	Undefined
Null	Undefined	**Ok**	Undefined	Undefined	Undefined	Undefined	Undefined
Boolean	Undefined	Undefined	**Ok**	Undefined	Undefined	Undefined	Undefined
Number	Undefined	Undefined	Undefined	**Ok**	Undefined	Undefined	Undefined
String	Undefined	Undefined	Undefined	Undefined	**Ok**	Undefined	Undefined
Object	Undefined	Undefined	Undefined	Undefined	Undefined	**Ok**	Undefined
Array	Undefined	Undefined	Undefined	Undefined	Undefined	Undefined	**Ok**

For comparison operators such as `>`, `>=`, `!=`, `<`, and `<=`, comparison across types or between two objects or arrays produces `Undefined`.

If the result of the scalar expression is `Undefined`, the item isn't included in the result, because `Undefined` doesn't equal `true`.

For example, the following query's comparison between a number and string value produces `Undefined`. Therefore, the filter does not include any results.

```
SELECT *
FROM c
WHERE 7 = 'a'
```

Logical (AND, OR and NOT) operators

Logical operators operate on Boolean values. The following tables show the logical truth tables for these operators:

OR operator

Returns `true` when either of the conditions is `true`.

	TRUE	FALSE	UNDEFINED
True	True	True	True
False	True	False	Undefined
Undefined	True	Undefined	Undefined

AND operator

Returns `true` when both expressions are `true`.

	TRUE	FALSE	UNDEFINED
True	True	False	Undefined
False	False	False	False
Undefined	Undefined	False	Undefined

NOT operator

Reverses the value of any Boolean expression.

	NOT
True	False
False	True
Undefined	Undefined

Operator Precedence

The logical operators `OR`, `AND`, and `NOT` have the precedence level shown below:

OPERATOR	PRIORITY
NOT	1
AND	2
OR	3

* operator

The special operator * projects the entire item as is. When used, it must be the only projected field. A query like `SELECT * FROM Families f` is valid, but `SELECT VALUE * FROM Families f` and `SELECT *, f.id FROM Families f` are not valid.

? and ?? operators

You can use the Ternary (?) and Coalesce (??) operators to build conditional expressions, as in programming languages like C# and JavaScript.

You can use the ? operator to construct new JSON properties on the fly. For example, the following query classifies grade levels into `elementary` or `other`:

```
SELECT (c.grade < 5)? "elementary": "other" AS gradeLevel
FROM Families.children[0] c
```

You can also nest calls to the ? operator, as in the following query:

```
SELECT (c.grade < 5)? "elementary": ((c.grade < 9)? "junior": "high") AS gradeLevel
FROM Families.children[0] c
```

As with other query operators, the ? operator excludes items if the referenced properties are missing or the types being compared are different.

Use the ?? operator to efficiently check for a property in an item when querying against semi-structured or mixed-type data. For example, the following query returns `lastName` if present, or `surname` if `lastName` isn't present.

```
SELECT f.lastName ?? f.surname AS familyName
FROM Families f
```

Next steps

- Keywords
- SELECT clause

Scalar expressions in Azure Cosmos DB SQL queries

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The SELECT clause supports scalar expressions. A scalar expression is a combination of symbols and operators that can be evaluated to obtain a single value. Examples of scalar expressions include: constants, property references, array element references, alias references, or function calls. Scalar expressions can be combined into complex expressions using operators.

Syntax

```
<scalar_expression> ::=
       <constant>
     | input_alias
     | parameter_name
     | <scalar_expression>.property_name
     | <scalar_expression>'['"property_name"|array_index']'
     | unary_operator <scalar_expression>
     | <scalar_expression> binary_operator <scalar_expression>
     | <scalar_expression> ? <scalar_expression> : <scalar_expression>
     | <scalar_function_expression>
     | <create_object_expression>
     | <create_array_expression>
     | (<scalar_expression>)

<scalar_function_expression> ::=
        'udf.' Udf_scalar_function([<scalar_expression>][,…n])
        | builtin_scalar_function([<scalar_expression>][,…n])

<create_object_expression> ::=
   '{' [{property_name | "property_name"} : <scalar_expression>][,…n] '}'

<create_array_expression> ::=
   '[' [<scalar_expression>][,…n] ']'
```

Arguments

- `<constant>`

  Represents a constant value. See Constants section for details.

- `input_alias`

  Represents a value defined by the `input_alias` introduced in the `FROM` clause.
  This value is guaranteed to not be **undefined** –**undefined** values in the input are skipped.

- `<scalar_expression>.property_name`

  Represents a value of the property of an object. If the property does not exist or property is referenced on a value, which is not an object, then the expression evaluates to **undefined** value.

- `<scalar_expression>'['"property_name"|array_index']'`

  Represents a value of the property with name `property_name` or array element with index `array_index` of

an array. If the property/array index does not exist or the property/array index is referenced on a value that is not an object/array, then the expression evaluates to undefined value.

- `unary_operator <scalar_expression>`

  Represents an operator that is applied to a single value. See Operators section for details.

- `<scalar_expression> binary_operator <scalar_expression>`

  Represents an operator that is applied to two values. See Operators section for details.

- `<scalar_function_expression>`

  Represents a value defined by a result of a function call.

- `udf_scalar_function`

  Name of the user-defined scalar function.

- `builtin_scalar_function`

  Name of the built-in scalar function.

- `<create_object_expression>`

  Represents a value obtained by creating a new object with specified properties and their values.

- `<create_array_expression>`

  Represents a value obtained by creating a new array with specified values as elements

- `parameter_name`

  Represents a value of the specified parameter name. Parameter names must have a single @ as the first character.

Remarks

When calling a built-in or user-defined scalar function, all arguments must be defined. If any of the arguments is undefined, the function will not be called and the result will be undefined.

When creating an object, any property that is assigned undefined value will be skipped and not included in the created object.

When creating an array, any element value that is assigned **undefined** value will be skipped and not included in the created object. This will cause the next defined element to take its place in such a way that the created array will not have skipped indexes.

Examples

```
SELECT ((2 + 11 % 7)-2)/3
```

The results are:

```
[{
  "$1": 1.33333
}]
```

In the following query, the result of the scalar expression is a Boolean:

```
SELECT f.address.city = f.address.state AS AreFromSameCityState
FROM Families f
```

The results are:

```
[
  {
    "AreFromSameCityState": false
  },
  {
    "AreFromSameCityState": true
  }
]
```

User-defined functions (UDFs) in Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

The SQL API provides support for user-defined functions (UDFs). With scalar UDFs, you can pass in zero or many arguments and return a single argument result. The API checks each argument for being legal JSON values.

UDF use cases

The API extends the SQL syntax to support custom application logic using UDFs. You can register UDFs with the SQL API, and reference them in SQL queries. Unlike stored procedures and triggers, UDFs are read-only.

Using UDFs, you can extend Azure Cosmos DB's query language. UDFs are a great way to express complex business logic in a query's projection.

However, we recommending avoiding UDFs when:

- An equivalent system function already exists in Azure Cosmos DB. System functions will always use fewer RU's than the equivalent UDF.
- The UDF is the only filter in the `WHERE` clause of your query. UDF's do not utilize the index so evaluating the UDF will require loading documents. Combining additional filter predicates that use the index, in combination with a UDF, in the `WHERE` clause will reduce the number of documents processed by the UDF.

If you must use the same UDF multiple times in a query, you should reference the UDF in a subquery, allowing you to use a JOIN expression to evaluate the UDF once but reference it many times.

Examples

The following example registers a UDF under an item container in the Cosmos database. The example creates a UDF whose name is `REGEX_MATCH`. It accepts two JSON string values, `input` and `pattern`, and checks if the first matches the pattern specified in the second using JavaScript's `string.match()` function.

```
UserDefinedFunction regexMatchUdf = new UserDefinedFunction
{
    Id = "REGEX_MATCH",
    Body = @"function (input, pattern) {
                return input.match(pattern) !== null;
            };",
};

UserDefinedFunction createdUdf = client.CreateUserDefinedFunctionAsync(
    UriFactory.CreateDocumentCollectionUri("myDatabase", "families"),
    regexMatchUdf).Result;
```

Now, use this UDF in a query projection. You must qualify UDFs with the case-sensitive prefix `udf.` when calling them from within queries.

```
SELECT udf.REGEX_MATCH(Families.address.city, ".*eattle")
FROM Families
```

The results are:

```
[
  {
    "$1": true
  },
  {
    "$1": false
  }
]
```

You can use the UDF qualified with the `udf.` prefix inside a filter, as in the following example:

```
SELECT Families.id, Families.address.city
FROM Families
WHERE udf.REGEX_MATCH(Families.address.city, ".*eattle")
```

The results are:

```
[{
    "id": "AndersenFamily",
    "city": "Seattle"
}]
```

In essence, UDFs are valid scalar expressions that you can use in both projections and filters.

To expand on the power of UDFs, look at another example with conditional logic:

```
   UserDefinedFunction seaLevelUdf = new UserDefinedFunction()
   {
       Id = "SEALEVEL",
       Body = @"function(city) {
               switch (city) {
                   case 'Seattle':
                       return 520;
                   case 'NY':
                       return 410;
                   case 'Chicago':
                       return 673;
                   default:
                       return -1;
                }"
        };

        UserDefinedFunction createdUdf = await client.CreateUserDefinedFunctionAsync(
            UriFactory.CreateDocumentCollectionUri("myDatabase", "families"),
            seaLevelUdf);
```

The following example exercises the UDF:

```
SELECT f.address.city, udf.SEALEVEL(f.address.city) AS seaLevel
FROM Families f
```

The results are:

```
[
 {
   "city": "Seattle",
   "seaLevel": 520
 },
 {
   "city": "NY",
   "seaLevel": 410
 }
]
```

If the properties referred to by the UDF parameters aren't available in the JSON value, the parameter is considered as undefined and the UDF invocation is skipped. Similarly, if the result of the UDF is undefined, it's not included in the result.

As the preceding examples show, UDFs integrate the power of JavaScript language with the SQL API. UDFs provide a rich programmable interface to do complex procedural, conditional logic with the help of built-in JavaScript runtime capabilities. The SQL API provides the arguments to the UDFs for each source item at the current WHERE or SELECT clause stage of processing. The result is seamlessly incorporated in the overall execution pipeline. In summary, UDFs are great tools to do complex business logic as part of queries.

Aggregate functions in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Aggregate functions perform a calculation on a set of values in the `SELECT` clause and return a single value. For example, the following query returns the count of items within a container:

```
SELECT COUNT(1)
FROM c
```

Types of aggregate functions

The SQL API supports the following aggregate functions. `SUM` and `AVG` operate on numeric values, and `COUNT`, `MIN`, and `MAX` work on numbers, strings, Booleans, and nulls.

FUNCTION	DESCRIPTION
AVG	Returns the average of the values in the expression.
COUNT	Returns the number of items in the expression.
MAX	Returns the maximum value in the expression.
MIN	Returns the minimum value in the expression.
SUM	Returns the sum of all the values in the expression.

You can also return only the scalar value of the aggregate by using the VALUE keyword. For example, the following query returns the count of values as a single number:

```
SELECT VALUE COUNT(1)
FROM Families f
```

The results are:

```
[ 2 ]
```

You can also combine aggregations with filters. For example, the following query returns the count of items with the address state of `WA`.

```
SELECT VALUE COUNT(1)
FROM Families f
WHERE f.address.state = "WA"
```

The results are:

```
[ 1 ]
```

Remarks

These aggregate system functions will benefit from a range index. If you expect to do an `AVG`, `COUNT`, `MAX`, `MIN`, or `SUM` on a property, you should include the relevant path in the indexing policy.

Next steps

- User defined functions

AVG (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This aggregate function returns the average of the values in the expression.

Syntax

```
AVG(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the average value of `propertyA`:

```
SELECT AVG(c.propertyA)
FROM c
```

Remarks

This system function will benefit from a range index. If any arguments in `AVG` are string, boolean, or null, the entire aggregate system function will return `undefined`. If any argument has an `undefined` value, it will not impact the `AVG` calculation.

Next steps

- Mathematical functions in Azure Cosmos DB
- System functions in Azure Cosmos DB
- Aggregate functions in Azure Cosmos DB

COUNT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This system function returns the count of the values in the expression.

Syntax

```
COUNT(<scalar_expr>)
```

Arguments

scalar_expr
Is any scalar expression

Return types

Returns a numeric expression.

Examples

The following example returns the total count of items in a container:

```
SELECT COUNT(1)
FROM c
```

COUNT can take any scalar expression as input. The below query will produce an equivalent results:

```
SELECT COUNT(2)
FROM c
```

Remarks

This system function will benefit from a range index for any properties in the query's filter.

Next steps

- Mathematical functions in Azure Cosmos DB
- System functions in Azure Cosmos DB
- Aggregate functions in Azure Cosmos DB

MAX (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This aggregate function returns the maximum of the values in the expression.

Syntax

```
MAX(<scalar_expr>)
```

Arguments

scalar_expr
Is a scalar expression.

Return types

Returns a scalar expression.

Examples

The following example returns the maximum value of `propertyA`:

```
SELECT MAX(c.propertyA)
FROM c
```

Remarks

This system function will benefit from a range index. The arguments in `MAX` can be number, string, boolean, or null. Any undefined values will be ignored.

When comparing different types data, the following priority order is used (in descending order):

- string
- number
- boolean
- null

Next steps

- Mathematical functions in Azure Cosmos DB
- System functions in Azure Cosmos DB
- Aggregate functions in Azure Cosmos DB

MIN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This aggregate function returns the minimum of the values in the expression.

Syntax

```
MIN(<scalar_expr>)
```

Arguments

scalar_expr
Is a scalar expression.

Return types

Returns a scalar expression.

Examples

The following example returns the minimum value of `propertyA`:

```
SELECT MIN(c.propertyA)
FROM c
```

Remarks

This system function will benefit from a range index. The arguments in `MIN` can be number, string, boolean, or null. Any undefined values will be ignored.

When comparing different types data, the following priority order is used (in ascending order):

- null
- boolean
- number
- string

Next steps

- Mathematical functions in Azure Cosmos DB
- System functions in Azure Cosmos DB
- Aggregate functions in Azure Cosmos DB

SUM (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This aggregate function returns the sum of the values in the expression.

Syntax

```
SUM(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the sum of `propertyA`:

```
SELECT SUM(c.propertyA)
FROM c
```

Remarks

This system function will benefit from a range index. If any arguments in `SUM` are string, boolean, or null, the entire aggregate system function will return `undefined`. If any argument has an `undefined` value, it will be not impact the `SUM` calculation.

Next steps

- Mathematical functions in Azure Cosmos DB
- System functions in Azure Cosmos DB
- Aggregate functions in Azure Cosmos DB

System functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Cosmos DB provides many built-in SQL functions. The categories of built-in functions are listed below.

FUNCTION GROUP	DESCRIPTION	OPERATIONS
Array functions	The array functions perform an operation on an array input value and return numeric, Boolean, or array value.	ARRAY_CONCAT, ARRAY_CONTAINS, ARRAY_LENGTH, ARRAY_SLICE
Date and Time functions	The date and time functions allow you to get the current UTC date and time in two forms; a numeric timestamp whose value is the Unix epoch in milliseconds or as a string which conforms to the ISO 8601 format.	GetCurrentDateTime, GetCurrentTimestamp
Mathematical functions	The mathematical functions each perform a calculation, usually based on input values that are provided as arguments, and return a numeric value.	ABS, ACOS, ASIN, ATAN, ATN2, CEILING, COS, COT, DEGREES, EXP, FLOOR, LOG, LOG10, PI, POWER, RADIANS, RAND, ROUND, SIGN, SIN, SQRT, SQUARE, TAN, TRUNC
Spatial functions	The spatial functions perform an operation on a spatial object input value and return a numeric or Boolean value.	ST_DISTANCE, ST_INTERSECTS, ST_ISVALID, ST_ISVALIDDETAILED, ST_WITHIN
String functions	The string functions perform an operation on a string input value and return a string, numeric or Boolean value.	CONCAT, CONTAINS, ENDSWITH, INDEX_OF, LEFT, LENGTH, LOWER, LTRIM, REGEXMATCHREPLACE, REPLICATE, REVERSE, RIGHT, RTRIM, STARTSWITH, StringToArray, StringToBoolean, StringToNull, StringToNumber, StringToObject, SUBSTRING, ToString, TRIM, UPPER
Type checking functions	The type checking functions allow you to check the type of an expression within SQL queries.	IS_ARRAY, IS_BOOL, IS_DEFINED, IS_NULL, IS_NUMBER, IS_OBJECT, IS_PRIMITIVE, IS_STRING

Built-in versus User Defined Functions (UDFs)

If you're currently using a user-defined function (UDF) for which a built-in function is now available, the corresponding built-in function will be quicker to run and more efficient.

Built-in versus ANSI SQL functions

The main difference between Cosmos DB functions and ANSI SQL functions is that Cosmos DB functions are designed to work well with schemaless and mixed-schema data. For example, if a property is missing or has a non-numeric value like `unknown`, the item is skipped instead of returning an error.

Array functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The array functions let you perform operations on arrays in Azure Cosmos DB.

Functions

The following scalar functions perform an operation on an array input value and return numeric, boolean or array value:

- ARRAY_CONCAT
- ARRAY_CONTAINS
- ARRAY_LENGTH
- ARRAY_SLICE

Next steps

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB
- User Defined Functions
- Aggregates

ARRAY_CONCAT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns an array that is the result of concatenating two or more array values.

Syntax

```
ARRAY_CONCAT (<arr_expr1>, <arr_expr2> [, <arr_exprN>])
```

Arguments

arr_expr
Is an array expression to concatenate to the other values. The `ARRAY_CONCAT` function requires at least two *arr_expr* arguments.

Return types

Returns an array expression.

Examples

The following example how to concatenate two arrays.

```
SELECT ARRAY_CONCAT(["apples", "strawberries"], ["bananas"]) AS arrayConcat
```

Here is the result set.

```
[{"arrayConcat": ["apples", "strawberries", "bananas"]}]
```

Remarks

This system function will not utilize the index.

Next steps

- Array functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ARRAY_CONTAINS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean indicating whether the array contains the specified value. You can check for a partial or full match of an object by using a boolean expression within the command.

Syntax

```
ARRAY_CONTAINS (<arr_expr>, <expr> [, bool_expr])
```

Arguments

arr_expr
Is the array expression to be searched.

expr
Is the expression to be found.

bool_expr
Is a boolean expression. If it evaluates to 'true' and if the specified search value is an object, the command checks for a partial match (the search object is a subset of one of the objects). If it evaluates to 'false', the command checks for a full match of all objects within the array. The default value if not specified is false.

Return types

Returns a Boolean value.

Examples

The following example how to check for membership in an array using `ARRAY_CONTAINS`.

```
SELECT
           ARRAY_CONTAINS(["apples", "strawberries", "bananas"], "apples") AS b1,
           ARRAY_CONTAINS(["apples", "strawberries", "bananas"], "mangoes") AS b2
```

Here is the result set.

```
[{"b1": true, "b2": false}]
```

The following example how to check for a partial match of a JSON in an array using ARRAY_CONTAINS.

```
SELECT
    ARRAY_CONTAINS([{"name": "apples", "fresh": true}, {"name": "strawberries", "fresh": true}], {"name":
"apples"}, true) AS b1,
    ARRAY_CONTAINS([{"name": "apples", "fresh": true}, {"name": "strawberries", "fresh": true}], {"name":
"apples"}) AS b2,
    ARRAY_CONTAINS([{"name": "apples", "fresh": true}, {"name": "strawberries", "fresh": true}], {"name":
"mangoes"}, true) AS b3
```

Here is the result set.

```
[{
  "b1": true,
  "b2": false,
  "b3": false
}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Array functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ARRAY_LENGTH (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the number of elements of the specified array expression.

Syntax

```
ARRAY_LENGTH(<arr_expr>)
```

Arguments

arr_expr
Is an array expression.

Return types

Returns a numeric expression.

Examples

The following example how to get the length of an array using `ARRAY_LENGTH`.

```
SELECT ARRAY_LENGTH(["apples", "strawberries", "bananas"]) AS len
```

Here is the result set.

```
[{"len": 3}]
```

Remarks

This system function will not utilize the index.

Next steps

- Array functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ARRAY_SLICE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns part of an array expression.

Syntax

```
ARRAY_SLICE (<arr_expr>, <num_expr> [, <num_expr>])
```

Arguments

arr_expr
Is any array expression.

num_expr
Zero-based numeric index at which to begin the array. Negative values may be used to specify the starting index relative to the last element of the array i.e. -1 references the last element in the array.

num_expr Optional numeric expression that sets the maximum number of elements in the resulting array.

Return types

Returns an array expression.

Examples

The following example shows how to get different slices of an array using `ARRAY_SLICE`.

```
SELECT
           ARRAY_SLICE(["apples", "strawberries", "bananas"], 1) AS s1,
           ARRAY_SLICE(["apples", "strawberries", "bananas"], 1, 1) AS s2,
           ARRAY_SLICE(["apples", "strawberries", "bananas"], -2, 1) AS s3,
           ARRAY_SLICE(["apples", "strawberries", "bananas"], -2, 2) AS s4,
           ARRAY_SLICE(["apples", "strawberries", "bananas"], 1, 0) AS s5,
           ARRAY_SLICE(["apples", "strawberries", "bananas"], 1, 1000) AS s6,
           ARRAY_SLICE(["apples", "strawberries", "bananas"], 1, -100) AS s7
```

Here is the result set.

```
[{
           "s1": ["strawberries", "bananas"],
           "s2": ["strawberries"],
           "s3": ["strawberries"],
           "s4": ["strawberries", "bananas"],
           "s5": [],
           "s6": ["strawberries", "bananas"],
           "s7": []
}]
```

Remarks

This system function will not utilize the index.

Next steps

- Array functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

Date and time functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The date and time functions let you perform DateTime and timestamp operations in Azure Cosmos DB.

Functions to obtain the date and time

The following scalar functions allow you to get the current UTC date and time in three forms: a string which conforms to the ISO 8601 format, a numeric timestamp whose value is the number of milliseconds which have elapsed since the Unix epoch, or numeric ticks whose value is the number of 100 nanosecond ticks which have elapsed since the Unix epoch:

- GetCurrentDateTime
- GetCurrentTimestamp
- GetCurrentTicks

Functions to work with DateTime values

The following functions allow you to easily manipulate DateTime, timestamp, and tick values:

- DateTimeAdd
- DateTimeDiff
- DateTimeFromParts
- DateTimePart
- DateTimeToTicks
- DateTimeToTimestamp
- TicksToDateTime
- TimestampToDateTime

Next steps

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB
- User Defined Functions
- Aggregates

DateTimeAdd (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns DateTime string value resulting from adding a specified number value (as a signed integer) to a specified DateTime string

Syntax

```
DateTimeAdd (<DateTimePart> , <numeric_expr> ,<DateTime>)
```

Arguments

DateTimePart

The part of date to which DateTimeAdd adds an integer number. This table lists all valid DateTimePart arguments:

DATETIMEPART	ABBREVIATIONS
Year	"year", "yyyy", "yy"
Month	"month", "mm", "m"
Day	"day", "dd", "d"
Hour	"hour", "hh"
Minute	"minute", "mi", "n"
Second	"second", "ss", "s"
Millisecond	"millisecond", "ms"
Microsecond	"microsecond", "mcs"
Nanosecond	"nanosecond", "ns"

numeric_expr

Is a signed integer value that will be added to the DateTimePart of the specified DateTime

DateTime

UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	

FORMAT	DESCRIPTION	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

Return types

Returns a UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

Remarks

DateTimeAdd will return `undefined` for the following reasons:

- The DateTimePart value specified is invalid
- The numeric_expr specified is not a valid integer
- The DateTime in the argument or result is not a valid ISO 8601 DateTime.

Examples

The following example adds 1 month to the DateTime: `2020-07-09T23:20:13.4575530Z`

```
SELECT DateTimeAdd("mm", 1, "2020-07-09T23:20:13.4575530Z") AS OneMonthLater
```

```
[
    {
        "OneMonthLater": "2020-08-09T23:20:13.4575530Z"
    }
]
```

The following example subtracts 2 hours from the DateTime: `2020-07-09T23:20:13.4575530Z`

```
SELECT DateTimeAdd("hh", -2, "2020-07-09T23:20:13.4575530Z") AS TwoHoursEarlier
```

```
[
    {
        "TwoHoursEarlier": "2020-07-09T21:20:13.4575530Z"
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

DateTimeDiff (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the count (as a signed integer value) of the specified DateTimePart boundaries crossed between the specified *StartDate* and *EndDate*.

Syntax

```
DateTimeDiff (<DateTimePart> , <StartDate> , <EndDate>)
```

Arguments

DateTimePart

The part of date to which DateTimeAdd adds an integer number. This table lists all valid DateTimePart arguments:

DATETIMEPART	ABBREVIATIONS
Year	"year", "yyyy", "yy"
Month	"month", "mm", "m"
Day	"day", "dd", "d"
Hour	"hour", "hh"
Minute	"minute", "mi", "n"
Second	"second", "ss", "s"
Millisecond	"millisecond", "ms"
Microsecond	"microsecond", "mcs"
Nanosecond	"nanosecond", "ns"

StartDate

UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	

FORMAT	DESCRIPTION	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

EndDate
UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ`

Return types

Returns a signed integer value.

Remarks

DateTimeDiff will return `undefined` for the following reasons:

- The DateTimePart value specified is invalid
- The StartDate or EndDate is not a valid ISO 8601 DateTime

DateTimeDiff will always return a signed integer value and is a measurement of the number of DateTimePart boundaries crossed, not measurement of the time interval.

Examples

The following example computes the number of day boundaries crossed between `2020-01-01T01:02:03.1234527Z` and `2020-01-03T01:02:03.1234567Z`.

```
SELECT DateTimeDiff("day", "2020-01-01T01:02:03.1234527Z", "2020-01-03T01:02:03.1234567Z") AS DifferenceInDays
```

```
[
    {
        "DifferenceInDays": 2
    }
]
```

The following example computes the number of year boundaries crossed between `2028-01-01T01:02:03.1234527Z` and `2020-01-03T01:02:03.1234567Z`.

```
SELECT DateTimeDiff("yyyy", "2028-01-01T01:02:03.1234527Z", "2020-01-03T01:02:03.1234567Z") AS
DifferenceInYears
```

```
[
    {
        "DifferenceInYears": -8
    }
]
```

The following example computes the number of hour boundaries crossed between `2020-01-01T01:00:00.1234527Z` and `2020-01-01T01:59:59.1234567Z`. Even though these DateTime values are over 0.99 hours apart, `DateTimeDiff` returns 0 because no hour boundaries were crossed.

```
SELECT DateTimeDiff("hh", "2020-01-01T01:00:00.1234527Z", "2020-01-01T01:59:59.1234567Z") AS DifferenceInHours
```

```
[
    {
        "DifferenceInHours": 0
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

DateTimeFromParts (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string DateTime value constructed from input values.

Syntax

```
DateTimeFromParts(<numberYear>, <numberMonth>, <numberDay> [, numberHour]  [, numberMinute]  [, numberSecond]
[, numberOfFractionsOfSecond])
```

Arguments

numberYear Integer value for the year in the format `YYYY`

numberMonth
Integer value for the month in the format `MM`

numberDay
Integer value for the day in the format `DD`

numberHour (optional) Integer value for the hour in the format `hh`

numberMinute (optional) Integer value for the minute in the format `mm`

numberSecond (optional) Integer value for the second in the format `ss`

numberOfFractionsOfSecond (optional) Integer value for the fractional of a second in the format `.fffffff`

Return types

Returns a UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	

FORMAT	DESCRIPTION	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

Remarks

If the specified integers would create an invalid DateTime, DateTimeFromParts will return `undefined`.

If an optional argument isn't specified, its value will be 0.

Examples

Here's an example that only includes required arguments to construct a DateTime:

```
SELECT DateTimeFromParts(2020, 9, 4) AS DateTime
```

```
[
    {
        "DateTime": "2020-09-04T00:00:00.0000000Z"
    }
]
```

Here's another example that also uses some optional arguments to construct a DateTime:

```
SELECT DateTimeFromParts(2020, 9, 4, 10, 52) AS DateTime
```

```
[
    {
        "DateTime": "2020-09-04T10:52:00.0000000Z"
    }
]
```

Here's another example that also uses all optional arguments to construct a DateTime:

```
SELECT DateTimeFromParts(2020, 9, 4, 10, 52, 12, 3456789) AS DateTime
```

```
[
    {
        "DateTime": "2020-09-04T10:52:12.3456789Z"
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

DateTimePart (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the value of the specified DateTimePart between the specified DateTime.

Syntax

```
DateTimePart (<DateTimePart> , <DateTime>)
```

Arguments

DateTimePart

The part of the date for which DateTimePart will return the value. This table lists all valid DateTimePart arguments:

DATETIMEPART	ABBREVIATIONS
Year	"year", "yyyy", "yy"
Month	"month", "mm", "m"
Day	"day", "dd", "d"
Hour	"hour", "hh"
Minute	"minute", "mi", "n"
Second	"second", "ss", "s"
Millisecond	"millisecond", "ms"
Microsecond	"microsecond", "mcs"
Nanosecond	"nanosecond", "ns"

DateTime

UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ`

Return types

Returns a positive integer value.

Remarks

DateTimePart will return `undefined` for the following reasons:

- The DateTimePart value specified is invalid
- The DateTime is not a valid ISO 8601 DateTime

This system function will not utilize the index.

Examples

Here's an example that returns the integer value of the month:

```
SELECT DateTimePart("m", "2020-01-02T03:04:05.6789123Z") AS MonthValue
```

```
[
    {
        "MonthValue": 1
    }
]
```

Here's an example that returns the number of microseconds:

```
SELECT DateTimePart("mcs", "2020-01-02T03:04:05.6789123Z") AS MicrosecondsValue
```

```
[
    {
        "MicrosecondsValue": 678912
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

DateTimeToTicks (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Converts the specified DateTime to ticks. A single tick represents one hundred nanoseconds or one ten-millionth of a second.

Syntax

```
DateTimeToTicks (<DateTime>)
```

Arguments

DateTime
UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ`

Return types

Returns a signed numeric value, the current number of 100-nanosecond ticks that have elapsed since the Unix epoch. In other words, DateTimeToTicks returns the number of 100-nanosecond ticks that have elapsed since 00:00:00 Thursday, 1 January 1970.

Remarks

DateTimeDateTimeToTicks will return `undefined` if the DateTime is not a valid ISO 8601 DateTime

This system function will not utilize the index.

Examples

Here's an example that returns the number of ticks:

```
SELECT DateTimeToTicks("2020-01-02T03:04:05.6789123Z") AS Ticks
```

```
[
    {
        "Ticks": 15779342456789124
    }
]
```

Here's an example that returns the number of ticks without specifying the number of fractional seconds:

```
SELECT DateTimeToTicks("2020-01-02T03:04:05Z") AS Ticks
```

```
[
    {
        "Ticks": 15779342450000000
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

DateTimeToTimestamp (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Converts the specified DateTime to a timestamp.

Syntax

```
DateTimeToTimestamp (<DateTime>)
```

Arguments

DateTime
UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

Return types

Returns a signed numeric value, the current number of milliseconds that have elapsed since the Unix epoch i.e. the number of milliseconds that have elapsed since 00:00:00 Thursday, 1 January 1970.

Remarks

DateTimeToTimestamp will return `undefined` if the DateTime value specified is invalid

Examples

The following example converts the DateTime to a timestamp:

```
SELECT DateTimeToTimestamp("2020-07-09T23:20:13.4575530Z") AS Timestamp
```

```
[
    {
        "Timestamp": 1594336813457
    }
]
```

Here's another example:

```
SELECT DateTimeToTimestamp("2020-07-09") AS Timestamp
```

```
[
    {
        "Timestamp": 1594252800000
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

GetCurrentDateTime (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the current UTC (Coordinated Universal Time) date and time as an ISO 8601 string.

Syntax

```
GetCurrentDateTime ()
```

Return types

Returns the current UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

Remarks

GetCurrentDateTime() is a nondeterministic function. The result returned is UTC. Precision is 7 digits, with an accuracy of 100 nanoseconds.

This system function will not utilize the index.

Examples

The following example shows how to get the current UTC Date Time using the GetCurrentDateTime() built-in function.

```
SELECT GetCurrentDateTime() AS currentUtcDateTime
```

Here is an example result set.

```
[{
  "currentUtcDateTime": "2019-05-03T20:36:17.1234567Z"
}]
```

Next steps

- Date and time functions Azure Cosmos DB

GetCurrentTicks (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the number of 100-nanosecond ticks that have elapsed since 00:00:00 Thursday, 1 January 1970.

Syntax

```
GetCurrentTicks ()
```

Return types

Returns a signed numeric value, the current number of 100-nanosecond ticks that have elapsed since the Unix epoch. In other words, GetCurrentTicks returns the number of 100 nanosecond ticks that have elapsed since 00:00:00 Thursday, 1 January 1970.

Remarks

GetCurrentTicks() is a nondeterministic function. The result returned is UTC (Coordinated Universal Time).

This system function will not utilize the index.

Examples

Here's an example that returns the current time, measured in ticks:

```
SELECT GetCurrentTicks() AS CurrentTimeInTicks
```

```
[
    {
        "CurrentTimeInTicks": 15973607943002652
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

GetCurrentTimestamp (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the number of milliseconds that have elapsed since 00:00:00 Thursday, 1 January 1970.

Syntax

```
GetCurrentTimestamp ()
```

Return types

Returns a signed numeric value, the current number of milliseconds that have elapsed since the Unix epoch i.e. the number of milliseconds that have elapsed since 00:00:00 Thursday, 1 January 1970.

Remarks

GetCurrentTimestamp() is a nondeterministic function. The result returned is UTC (Coordinated Universal Time).

This system function will not utilize the index.

Examples

The following example shows how to get the current timestamp using the GetCurrentTimestamp() built-in function.

```
SELECT GetCurrentTimestamp() AS currentUtcTimestamp
```

Here is an example result set.

```
[{
  "currentUtcTimestamp": 1556916469065
}]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

TicksToDateTime (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Converts the specified ticks value to a DateTime.

Syntax

```
TicksToDateTime (<Ticks>)
```

Arguments

Ticks

A signed numeric value, the current number of 100 nanosecond ticks that have elapsed since the Unix epoch. In other words, it is the number of 100 nanosecond ticks that have elapsed since 00:00:00 Thursday, 1 January 1970.

Return types

Returns the UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

Remarks

TicksToDateTime will return `undefined` if the ticks value specified is invalid.

Examples

The following example converts the ticks to a DateTime:

```
SELECT TicksToDateTime(15943368134575530) AS DateTime
```

```
[
    {
        "DateTime": "2020-07-09T23:20:13.4575530Z"
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

TimestampToDateTime (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Converts the specified timestamp value to a DateTime.

Syntax

```
TimestampToDateTime (<Timestamp>)
```

Arguments

Timestamp

A signed numeric value, the current number of milliseconds that have elapsed since the Unix epoch. In other words, the number of milliseconds that have elapsed since 00:00:00 Thursday, 1 January 1970.

Return types

Returns the UTC date and time ISO 8601 string value in the format `YYYY-MM-DDThh:mm:ss.fffffffZ` where:

FORMAT	DESCRIPTION	
YYYY	four-digit year	
MM	two-digit month (01 = January, etc.)	
DD	two-digit day of month (01 through 31)	
T	signifier for beginning of time elements	
hh	two-digit hour (00 through 23)	
mm	two-digit minutes (00 through 59)	
ss	two-digit seconds (00 through 59)	
.fffffff	seven-digit fractional seconds	
Z	UTC (Coordinated Universal Time) designator	

For more information on the ISO 8601 format, see ISO_8601

Remarks

TimestampToDateTime will return `undefined` if the timestamp value specified is invalid.

Examples

The following example converts the timestamp to a DateTime:

```
SELECT TimestampToDateTime(1594227912345) AS DateTime
```

```
[
    {
        "DateTime": "2020-07-08T17:05:12.3450000Z"
    }
]
```

Next steps

- Date and time functions Azure Cosmos DB
- System functions Azure Cosmos DB

Mathematical functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The mathematical functions each perform a calculation, based on input values that are provided as arguments, and return a numeric value.

You can run queries like the following example:

```
SELECT VALUE ABS(-4)
```

The result is:

```
[4]
```

Functions

The following supported built-in mathematical functions perform a calculation, usually based on input arguments, and return a numeric expression:

- ABS
- ACOS
- ASIN
- ATAN
- ATN2
- CEILING
- COS
- COT
- DEGREES
- EXP
- FLOOR
- LOG
- LOG10
- PI
- POWER
- RADIANS
- RAND
- ROUND
- SIGN
- SIN
- SQRT
- SQUARE
- TAN
- TRUNC

All mathematical functions, except for RAND, are deterministic functions. This means they return the same results each time they are called with a specific set of input values.

Next steps

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB
- User Defined Functions
- Aggregates

ABS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the absolute (positive) value of the specified numeric expression.

Syntax

```
ABS (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example shows the results of using the `ABS` function on three different numbers.

```
SELECT ABS(-1) AS abs1, ABS(0) AS abs2, ABS(1) AS abs3
```

Here is the result set.

```
[{abs1: 1, abs2: 0, abs3: 1}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ACOS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the angle, in radians, whose cosine is the specified numeric expression; also called arccosine.

Syntax

```
ACOS(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the `ACOS` of -1.

```
SELECT ACOS(-1) AS acos
```

Here is the result set.

```
[{"acos": 3.1415926535897931}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ASIN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the angle, in radians, whose sine is the specified numeric expression. This is also called arcsine.

Syntax

```
ASIN(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the `ASIN` of -1.

```
SELECT ASIN(-1) AS asin
```

Here is the result set.

```
[{"asin": -1.5707963267948966}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ATAN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the angle, in radians, whose tangent is the specified numeric expression. This is also called arctangent.

Syntax

```
ATAN(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the `ATAN` of the specified value.

```
SELECT ATAN(-45.01) AS atan
```

Here is the result set.

```
[{"atan": -1.5485826962062663}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ATN2 (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the principal value of the arc tangent of y/x, expressed in radians.

Syntax

```
ATN2(<numeric_expr>, <numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example calculates the ATN2 for the specified x and y components.

```
SELECT ATN2(35.175643, 129.44) AS atn2
```

Here is the result set.

```
[{"atn2": 1.3054517947300646}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

CEILING (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the smallest integer value greater than, or equal to, the specified numeric expression.

Syntax

```
CEILING (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example shows positive numeric, negative, and zero values with the `CEILING` function.

```
SELECT CEILING(123.45) AS c1, CEILING(-123.45) AS c2, CEILING(0.0) AS c3
```

Here is the result set.

```
[{c1: 124, c2: -123, c3: 0}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

COS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the trigonometric cosine of the specified angle, in radians, in the specified expression.

Syntax

```
COS(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example calculates the `cos` of the specified angle.

```
SELECT COS(14.78) AS cos
```

Here is the result set.

```
[{"cos": -0.59946542619465426}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

COT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the trigonometric cotangent of the specified angle, in radians, in the specified numeric expression.

Syntax

```
COT(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example calculates the `COT` of the specified angle.

```
SELECT COT(124.1332) AS cot
```

Here is the result set.

```
[{"cot": -0.040311998371148884}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

DEGREES (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the corresponding angle in degrees for an angle specified in radians.

Syntax

```
DEGREES (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the number of degrees in an angle of PI/2 radians.

```
SELECT DEGREES(PI()/2) AS degrees
```

Here is the result set.

```
[{"degrees": 90}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

EXP (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the exponential value of the specified numeric expression.

Syntax

```
EXP (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Remarks

The constant **e** (2.718281...), is the base of natural logarithms.

The exponent of a number is the constant **e** raised to the power of the number. For example, EXP(1.0) = e^1.0 = 2.71828182845905 and EXP(10) = e^10 = 22026.4657948067.

The exponential of the natural logarithm of a number is the number itself: EXP (LOG (n)) = n. And the natural logarithm of the exponential of a number is the number itself: LOG (EXP (n)) = n.

Examples

The following example declares a variable and returns the exponential value of the specified variable (10).

```
SELECT EXP(10) AS exp
```

Here is the result set.

```
[{exp: 22026.465794806718}]
```

The following example returns the exponential value of the natural logarithm of 20 and the natural logarithm of the exponential of 20. Because these functions are inverse functions of one another, the return value with rounding for floating point math in both cases is 20.

```
SELECT EXP(LOG(20)) AS exp1, LOG(EXP(20)) AS exp2
```

Here is the result set.

```
[{exp1: 19.999999999999996, exp2: 20}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

FLOOR (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the largest integer less than or equal to the specified numeric expression.

Syntax

```
FLOOR (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example shows positive numeric, negative, and zero values with the `FLOOR` function.

```
SELECT FLOOR(123.45) AS fl1, FLOOR(-123.45) AS fl2, FLOOR(0.0) AS fl3
```

Here is the result set.

```
[{fl1: 123, fl2: -124, fl3: 0}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

LOG (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the natural logarithm of the specified numeric expression.

Syntax

```
LOG (<numeric_expr> [, <base>])
```

Arguments

numeric_expr
Is a numeric expression.

base
Optional numeric argument that sets the base for the logarithm.

Return types

Returns a numeric expression.

Remarks

By default, LOG() returns the natural logarithm. You can change the base of the logarithm to another value by using the optional base parameter.

The natural logarithm is the logarithm to the base **e**, where **e** is an irrational constant approximately equal to 2.718281828.

The natural logarithm of the exponential of a number is the number itself: LOG(EXP(n)) = n. And the exponential of the natural logarithm of a number is the number itself: EXP(LOG(n)) = n.

This system function will not utilize the index.

Examples

The following example declares a variable and returns the logarithm value of the specified variable (10).

```
SELECT LOG(10) AS log
```

Here is the result set.

```
[{log: 2.3025850929940459}]
```

The following example calculates the `LOG` for the exponent of a number.

```
SELECT EXP(LOG(10)) AS expLog
```

Here is the result set.

```
[{expLog: 10.000000000000002}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

LOG10 (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the base-10 logarithm of the specified numeric expression.

Syntax

```
LOG10 (<numeric_expr>)
```

Arguments

numeric_expression
Is a numeric expression.

Return types

Returns a numeric expression.

Remarks

The LOG10 and POWER functions are inversely related to one another. For example, 10 ^ LOG10(n) = n. This system function will not utilize the index.

Examples

The following example declares a variable and returns the LOG10 value of the specified variable (100).

```
SELECT LOG10(100) AS log10
```

Here is the result set.

```
[{log10: 2}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

PI (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the constant value of PI.

Syntax

```
PI ()
```

Return types

Returns a numeric expression.

Examples

The following example returns the value of `PI`.

```
SELECT PI() AS pi
```

Here is the result set.

```
[{"pi": 3.1415926535897931}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

POWER (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the value of the specified expression to the specified power.

Syntax

```
POWER (<numeric_expr1>, <numeric_expr2>)
```

Arguments

numeric_expr1
Is a numeric expression.

numeric_expr2
Is the power to which to raise *numeric_expr1*.

Return types

Returns a numeric expression.

Examples

The following example demonstrates raising a number to the power of 3 (the cube of the number).

```
SELECT POWER(2, 3) AS pow1, POWER(2.5, 3) AS pow2
```

Here is the result set.

```
[{pow1: 8, pow2: 15.625}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

RADIANS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns radians when a numeric expression, in degrees, is entered.

Syntax

```
RADIANS (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example takes a few angles as input and returns their corresponding radian values.

```
SELECT RADIANS(-45.01) AS r1, RADIANS(-181.01) AS r2, RADIANS(0) AS r3, RADIANS(0.1472738) AS r4,
RADIANS(197.1099392) AS r5
```

Here is the result set.

```
[{
       "r1": -0.7855726963226477,
       "r2": -3.1592204790349356,
       "r3": 0,
       "r4": 0.0025704127119236249,
       "r5": 3.4402174274458375
   }]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

RAND (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a randomly generated numeric value from [0,1).

Syntax

```
RAND ()
```

Return types

Returns a numeric expression.

Remarks

`RAND` is a nondeterministic function. Repetitive calls of `RAND` do not return the same results. This system function will not utilize the index.

Examples

The following example returns a randomly generated numeric value.

```
SELECT RAND() AS rand
```

Here is the result set.

```
[{"rand": 0.87860053195618093}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ROUND (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a numeric value, rounded to the closest integer value.

Syntax

```
ROUND(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Remarks

The rounding operation performed follows midpoint rounding away from zero. If the input is a numeric expression which falls exactly between two integers then the result will be the closest integer value away from zero. This system function will benefit from a range index.

<NUMERIC_EXPR>	ROUNDED	
-6.5000	-7	
-0.5	-1	
0.5	1	
6.5000	7	

Examples

The following example rounds the following positive and negative numbers to the nearest integer.

```
SELECT ROUND(2.4) AS r1, ROUND(2.6) AS r2, ROUND(2.5) AS r3, ROUND(-2.4) AS r4, ROUND(-2.6) AS r5
```

Here is the result set.

```
[{r1: 2, r2: 3, r3: 3, r4: -2, r5: -3}]
```

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

SIGN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the positive (+1), zero (0), or negative (-1) sign of the specified numeric expression.

Syntax

```
SIGN(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the `SIGN` values of numbers from -2 to 2.

```
SELECT SIGN(-2) AS s1, SIGN(-1) AS s2, SIGN(0) AS s3, SIGN(1) AS s4, SIGN(2) AS s5
```

Here is the result set.

```
[{s1: -1, s2: -1, s3: 0, s4: 1, s5: 1}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

SIN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the trigonometric sine of the specified angle, in radians, in the specified expression.

Syntax

```
SIN(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example calculates the `SIN` of the specified angle.

```
SELECT SIN(45.175643) AS sin
```

Here is the result set.

```
[{"sin": 0.929607286611012}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

SQRT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the square root of the specified numeric value.

Syntax

```
SQRT(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the square roots of numbers 1-3.

```
SELECT SQRT(1) AS s1, SQRT(2.0) AS s2, SQRT(3) AS s3
```

Here is the result set.

```
[{s1: 1, s2: 1.4142135623730952, s3: 1.7320508075688772}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

SQUARE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the square of the specified numeric value.

Syntax

```
SQUARE(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example returns the squares of numbers 1-3.

```
SELECT SQUARE(1) AS s1, SQUARE(2.0) AS s2, SQUARE(3) AS s3
```

Here is the result set.

```
[{s1: 1, s2: 4, s3: 9}]
```

Remarks

This system function will not utilize the index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

TAN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the tangent of the specified angle, in radians, in the specified expression.

Syntax

```
TAN (<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example calculates the tangent of PI()/2.

```
SELECT TAN(PI()/2) AS tan
```

Here is the result set.

```
[{"tan": 16331239353195370 }]
```

Remarks

This system function will not utilize the index.

Next steps

TRUNC (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a numeric value, truncated to the closest integer value.

Syntax

```
TRUNC(<numeric_expr>)
```

Arguments

numeric_expr
Is a numeric expression.

Return types

Returns a numeric expression.

Examples

The following example truncates the following positive and negative numbers to the nearest integer value.

```
SELECT TRUNC(2.4) AS t1, TRUNC(2.6) AS t2, TRUNC(2.5) AS t3, TRUNC(-2.4) AS t4, TRUNC(-2.6) AS t5
```

Here is the result set.

```
[{t1: 2, t2: 2, t3: 2, t4: -2, t5: -2}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Mathematical functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

Spatial functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Cosmos DB supports the following Open Geospatial Consortium (OGC) built-in functions for geospatial querying.

Functions

The following scalar functions perform an operation on a spatial object input value and return a numeric or Boolean value.

- ST_DISTANCE
- ST_INTERSECTS
- ST_ISVALID
- ST_ISVALIDDETAILED
- ST_WITHIN

Next steps

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB
- User Defined Functions
- Aggregates

ST_DISTANCE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the distance between the two GeoJSON Point, Polygon, MultiPolygon or LineString expressions. To learn more, see the Geospatial and GeoJSON location data article.

Syntax

```
ST_DISTANCE (<spatial_expr>, <spatial_expr>)
```

Arguments

spatial_expr
Is any valid GeoJSON Point, Polygon, or LineString object expression.

Return types

Returns a numeric expression containing the distance. This is expressed in meters for the default reference system.

Examples

The following example shows how to return all family documents that are within 30 km of the specified location using the `ST_DISTANCE` built-in function. .

```
SELECT f.id
FROM Families f
WHERE ST_DISTANCE(f.location, {'type': 'Point', 'coordinates':[31.9, -4.8]}) < 30000
```

Here is the result set.

```
[{
  "id": "WakefieldFamily"
}]
```

Remarks

This system function will benefit from a geospatial index.

Next steps

- Spatial functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ST_WITHIN (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean expression indicating whether the GeoJSON object (Point, Polygon, MultiPolygon, or LineString) specified in the first argument is within the GeoJSON (Point, Polygon, MultiPolygon, or LineString) in the second argument.

Syntax

```
ST_WITHIN (<spatial_expr>, <spatial_expr>)
```

Arguments

spatial_expr
Is a GeoJSON Point, Polygon, or LineString object expression.

Return types

Returns a Boolean value.

Examples

The following example shows how to find all family documents within a polygon using `ST_WITHIN`.

```
SELECT f.id
FROM Families f
WHERE ST_WITHIN(f.location, {
    'type':'Polygon',
    'coordinates': [[[31.8, -5], [32, -5], [32, -4.7], [31.8, -4.7], [31.8, -5]]]
})
```

Here is the result set.

```
[{ "id": "WakefieldFamily" }]
```

Remarks

This system function will benefit from a geospatial index.

Next steps

- Spatial functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ST_INTERSECTS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean expression indicating whether the GeoJSON object (Point, Polygon, MultiPolygon, or LineString) specified in the first argument intersects the GeoJSON (Point, Polygon, MultiPolygon, or LineString) in the second argument.

Syntax

```
ST_INTERSECTS (<spatial_expr>, <spatial_expr>)
```

Arguments

spatial_expr
Is a GeoJSON Point, Polygon, or LineString object expression.

Return types

Returns a Boolean value.

Examples

The following example shows how to find all areas that intersect with the given polygon.

```
SELECT a.id
FROM Areas a
WHERE ST_INTERSECTS(a.location, {
    'type':'Polygon',
    'coordinates': [[[31.8, -5], [32, -5], [32, -4.7], [31.8, -4.7], [31.8, -5]]]
})
```

Here is the result set.

```
[{ "id": "IntersectingPolygon" }]
```

Remarks

This system function will benefit from a geospatial index.

Next steps

- Spatial functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ST_ISVALID (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating whether the specified GeoJSON Point, Polygon, MultiPolygon, or LineString expression is valid.

Syntax

```
ST_ISVALID(<spatial_expr>)
```

Arguments

spatial_expr
Is a GeoJSON Point, Polygon, or LineString expression.

Return types

Returns a Boolean expression.

Examples

The following example shows how to check if a point is valid using ST_VALID.

For example, this point has a latitude value that's not in the valid range of values [-90, 90], so the query returns false.

For polygons, the GeoJSON specification requires that the last coordinate pair provided should be the same as the first, to create a closed shape. Points within a polygon must be specified in counter-clockwise order. A polygon specified in clockwise order represents the inverse of the region within it.

```
SELECT ST_ISVALID({ "type": "Point", "coordinates": [31.9, -132.8] }) AS b
```

Here is the result set.

```
[{ "b": false }]
```

Next steps

- Spatial functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ST_ISVALIDDETAILED (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a JSON value containing a Boolean value if the specified GeoJSON Point, Polygon, or LineString expression is valid, and if invalid, additionally the reason as a string value.

Syntax

```
ST_ISVALIDDETAILED(<spatial_expr>)
```

Arguments

spatial_expr
Is a GeoJSON point or polygon expression.

Return types

Returns a JSON value containing a Boolean value if the specified GeoJSON point or polygon expression is valid, and if invalid, additionally the reason as a string value.

Examples

The following example how to check validity (with details) using `ST_ISVALIDDETAILED`.

```
SELECT ST_ISVALIDDETAILED({
  "type": "Polygon",
  "coordinates": [[ [ 31.8, -5 ], [ 31.8, -4.7 ], [ 32, -4.7 ], [ 32, -5 ] ]]
}) AS b
```

Here is the result set.

```
[{
  "b": {
    "valid": false,
    "reason": "The Polygon input is not valid because the start and end points of the ring number 1 are not
the same. Each ring of a polygon must have the same start and end points."
  }
}]
```

Next steps

- Spatial functions Azure Cosmos DB
- System functions Azure Cosmos DB

String functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The string functions let you perform operations on strings in Azure Cosmos DB.

Functions

The following scalar functions perform an operation on a string input value and return a string, numeric, or Boolean value:

- CONCAT
- CONTAINS
- ENDSWITH
- INDEX_OF
- LEFT
- LENGTH
- LOWER
- LTRIM
- REGEXMATCH
- REPLACE
- REPLICATE
- REVERSE
- RIGHT
- RTRIM
- STARTSWITH
- StringToArray
- StringToBoolean
- StringToNull
- StringToNumber
- StringToObject
- SUBSTRING
- ToString
- TRIM
- UPPER

Next steps

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB
- User Defined Functions
- Aggregates

CONCAT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string that is the result of concatenating two or more string values.

Syntax

```
CONCAT(<str_expr1>, <str_expr2> [, <str_exprN>])
```

Arguments

str_expr
Is a string expression to concatenate to the other values. The `CONCAT` function requires at least two *str_expr* arguments.

Return types

Returns a string expression.

Examples

The following example returns the concatenated string of the specified values.

```
SELECT CONCAT("abc", "def") AS concat
```

Here is the result set.

```
[{"concat": "abcdef"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

CONTAINS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean indicating whether the first string expression contains the second.

Syntax

```
CONTAINS(<str_expr1>, <str_expr2> [, <bool_expr>])
```

Arguments

str_expr1
Is the string expression to be searched.

str_expr2
Is the string expression to find.

bool_expr Optional value for ignoring case. When set to true, CONTAINS will do a case-insensitive search. When unspecified, this value is false.

Return types

Returns a Boolean expression.

Examples

The following example checks if "abc" contains "ab" and if "abc" contains "A".

```
SELECT CONTAINS("abc", "ab", false) AS c1, CONTAINS("abc", "A", false) AS c2, CONTAINS("abc", "A", true) AS c3
```

Here is the result set.

```
[
    {
        "c1": true,
        "c2": false,
        "c3": true
    }
]
```

Remarks

This system function will benefit from a range index.

The RU consumption of Contains will increase as the cardinality of the property in the system function increases. In other words, if you are checking whether a property value contains a certain string, the query RU charge will depend on the number of possible values for that property.

For example, consider two properties: town and country. The cardinality of town is 5,000 and the cardinality of country is 200. Here are two example queries:

```
SELECT * FROM c WHERE CONTAINS(c.town, "Red", false)
```

```
SELECT * FROM c WHERE CONTAINS(c.country, "States", false)
```

The first query will likely use more RUs than the second query because the cardinality of town is higher than country.

If the property size in Contains is greater than 1 KB for some documents, the query engine will need to load those documents. In this case, the query engine won't be able to fully evaluate Contains with an index. The RU charge for Contains will be high if you have a large number of documents with property sizes more than 1 KB.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ENDSWITH (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean indicating whether the first string expression ends with the second.

Syntax

```
ENDSWITH(<str_expr1>, <str_expr2> [, <bool_expr>])
```

Arguments

str_expr1
Is a string expression.

str_expr2
Is a string expression to be compared to the end of *str_expr1*.

bool_expr Optional value for ignoring case. When set to true, ENDSWITH will do a case-insensitive search. When unspecified, this value is false.

Return types

Returns a Boolean expression.

Examples

The following example checks if the string "abc" ends with "b" and "bC".

```
SELECT ENDSWITH("abc", "b", false) AS e1, ENDSWITH("abc", "bC", false) AS e2, ENDSWITH("abc", "bC", true) AS
e3
```

Here is the result set.

```
[
    {
        "e1": false,
        "e2": false,
        "e3": true
    }
]
```

Remarks

This system function will benefit from a range index.

The RU consumption of EndsWith will increase as the cardinality of the property in the system function increases. In other words, if you are checking whether a property value ends with a certain string, the query RU charge will depend on the number of possible values for that property.

For example, consider two properties: town and country. The cardinality of town is 5,000 and the cardinality of country is 200. Here are two example queries:

```
SELECT * FROM c WHERE ENDSWITH(c.town, "York", false)
```

```
SELECT * FROM c WHERE ENDSWITH(c.country, "States", false)
```

The first query will likely use more RUs than the second query because the cardinality of town is higher than country.

If the property size in EndsWith is greater than 1 KB for some documents, the query engine will need to load those documents. In this case, the query engine won't be able to fully evaluate EndsWith with an index. The RU charge for EndsWith will be high if you have a large number of documents with property sizes greater than 1 KB.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

INDEX_OF (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the starting position of the first occurrence of the second string expression within the first specified string expression, or -1 if the string is not found.

Syntax

```
INDEX_OF(<str_expr1>, <str_expr2> [, <numeric_expr>])
```

Arguments

str_expr1
Is the string expression to be searched.

str_expr2
Is the string expression to search for.

numeric_expr Optional numeric expression that sets the position the search will start. The first position in *str_expr1* is 0.

Return types

Returns a numeric expression.

Examples

The following example returns the index of various substrings inside "abc".

```
SELECT INDEX_OF("abc", "ab") AS i1, INDEX_OF("abc", "b") AS i2, INDEX_OF("abc", "c") AS i3
```

Here is the result set.

```
[{"i1": 0, "i2": 1, "i3": -1}]
```

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

LEFT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the left part of a string with the specified number of characters.

Syntax

```
LEFT(<str_expr>, <num_expr>)
```

Arguments

str_expr
Is the string expression to extract characters from.

num_expr
Is a numeric expression which specifies the number of characters.

Return types

Returns a string expression.

Examples

The following example returns the left part of "abc" for various length values.

```
SELECT LEFT("abc", 1) AS l1, LEFT("abc", 2) AS l2
```

Here is the result set.

```
[{"l1": "a", "l2": "ab"}]
```

Remarks

This system function will benefit from a range index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

LENGTH (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the number of characters of the specified string expression.

Syntax

```
LENGTH(<str_expr>)
```

Arguments

str_expr
Is the string expression to be evaluated.

Return types

Returns a numeric expression.

Examples

The following example returns the length of a string.

```
SELECT LENGTH("abc") AS len
```

Here is the result set.

```
[{"len": 3}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

LOWER (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string expression after converting uppercase character data to lowercase.

The LOWER system function does not utilize the index. If you plan to do frequent case insensitive comparisons, the LOWER system function may consume a significant amount of RU's. If this is the case, instead of using the LOWER system function to normalize data each time for comparisons, you can normalize the casing upon insertion. Then a query such as SELECT * FROM c WHERE LOWER(c.name) = 'bob' simply becomes SELECT * FROM c WHERE c.name = 'bob'.

Syntax

```
LOWER(<str_expr>)
```

Arguments

str_expr
Is a string expression.

Return types

Returns a string expression.

Examples

The following example shows how to use `LOWER` in a query.

```
SELECT LOWER("Abc") AS lower
```

Here is the result set.

```
[{"lower": "abc"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

LTRIM (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string expression after it removes leading blanks.

Syntax

```
LTRIM(<str_expr>)
```

Arguments

str_expr
Is a string expression.

Return types

Returns a string expression.

Examples

The following example shows how to use `LTRIM` inside a query.

```
SELECT LTRIM("  abc") AS l1, LTRIM("abc") AS l2, LTRIM("abc   ") AS l3
```

Here is the result set.

```
[{"l1": "abc", "l2": "abc", "l3": "abc   "}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

REGEXMATCH (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Provides regular expression capabilities. Regular expressions are a concise and flexible notation for finding patterns of text. Azure Cosmos DB uses PERL compatible regular expressions (PCRE).

Syntax

```
RegexMatch(<str_expr1>, <str_expr2>, [, <str_expr3>])
```

Arguments

str_expr1
Is the string expression to be searched.

str_expr2
Is the regular expression.

str_expr3
Is the string of selected modifiers to use with the regular expression. This string value is optional. If you'd like to run RegexMatch with no modifiers, you can either add an empty string or omit entirely.

You can learn about syntax for creating regular expressions in Perl.

Azure Cosmos DB supports the following four modifiers:

MODIFIER	DESCRIPTION
`m`	Treat the string expression to be searched as multiple lines. Without this option, "^" and "$" will match at the beginning or end of the string and not each individual line.
`s`	Allow "." to match any character, including a newline character.
`i`	Ignore case when pattern matching.
`x`	Ignore all whitespace characters.

Return types

Returns a Boolean expression. Returns undefined if the string expression to be searched, the regular expression, or the selected modifiers are invalid.

Examples

The following simple RegexMatch example checks the string "abcd" for regular expression match using a few different modifiers.

```
SELECT RegexMatch ("abcd", "ABC", "") AS NoModifiers,
RegexMatch ("abcd", "ABC", "i") AS CaseInsensitive,
RegexMatch ("abcd", "ab.", "") AS WildcardCharacter,
RegexMatch ("abcd", "ab c", "x") AS IgnoreWhiteSpace,
RegexMatch ("abcd", "aB c", "ix") AS CaseInsensitiveAndIgnoreWhiteSpace
```

Here is the result set.

```
[
    {
        "NoModifiers": false,
        "CaseInsensitive": true,
        "WildcardCharacter": true,
        "IgnoreWhiteSpace": true,
        "CaseInsensitiveAndIgnoreWhiteSpace": true
    }
]
```

With RegexMatch, you can use metacharacters to do more complex string searches that wouldn't otherwise be possible with the StartsWith, EndsWith, Contains, or StringEquals system functions. Here are some additional examples, which you can run using the nutrition data set available through the Azure Cosmos DB Query Playground.

> **NOTE**
> If you need to use a metacharacter in a regular expression and don't want it to have special meaning, you should escape the metacharacter using `\`.

Check items that have a description that contains the word "salt" exactly once:

```
SELECT *
FROM c
WHERE RegexMatch (c.description, "salt{1}","")
```

Check items that have a description that contain a number between 0 and 99:

```
SELECT *
FROM c
WHERE RegexMatch (c.description, "[0-99]","")
```

Check items that have a description that contain four letter words starting with "S" or "s":

```
SELECT *
FROM c
WHERE RegexMatch (c.description, " s... ","i")
```

Remarks

This system function will benefit from a range index if the regular expression can be broken down into either StartsWith, EndsWith, Contains, or StringEquals system functions.

Next steps

- String functions Azure Cosmos DB

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

REPLACE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Replaces all occurrences of a specified string value with another string value.

Syntax

```
REPLACE(<str_expr1>, <str_expr2>, <str_expr3>)
```

Arguments

str_expr1
Is the string expression to be searched.

str_expr2
Is the string expression to be found.

str_expr3
Is the string expression to replace occurrences of *str_expr2* in *str_expr1*.

Return types

Returns a string expression.

Examples

The following example shows how to use `REPLACE` in a query.

```
SELECT REPLACE("This is a Test", "Test", "desk") AS replace
```

Here is the result set.

```
[{"replace": "This is a desk"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

REPLICATE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Repeats a string value a specified number of times.

Syntax

```
REPLICATE(<str_expr>, <num_expr>)
```

Arguments

str_expr
Is a string expression.

num_expr
Is a numeric expression. If *num_expr* is negative or non-finite, the result is undefined.

Return types

Returns a string expression.

Remarks

The maximum length of the result is 10,000 characters i.e. (length(*str_expr*) * *num_expr*) <= 10,000. This system function will not utilize the index.

Examples

The following example shows how to use `REPLICATE` in a query.

```
SELECT REPLICATE("a", 3) AS replicate
```

Here is the result set.

```
[{"replicate": "aaa"}]
```

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

REVERSE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the reverse order of a string value.

Syntax

```
REVERSE(<str_expr>)
```

Arguments

str_expr
Is a string expression.

Return types

Returns a string expression.

Examples

The following example shows how to use `REVERSE` in a query.

```
SELECT REVERSE("Abc") AS reverse
```

Here is the result set.

```
[{"reverse": "cbA"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

RIGHT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns the right part of a string with the specified number of characters.

Syntax

```
RIGHT(<str_expr>, <num_expr>)
```

Arguments

str_expr
Is the string expression to extract characters from.

num_expr
Is a numeric expression which specifies the number of characters.

Return types

Returns a string expression.

Examples

The following example returns the right part of "abc" for various length values.

```
SELECT RIGHT("abc", 1) AS r1, RIGHT("abc", 2) AS r2
```

Here is the result set.

```
[{"r1": "c", "r2": "bc"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

RTRIM (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string expression after it removes trailing blanks.

Syntax

```
RTRIM(<str_expr>)
```

Arguments

str_expr
Is any valid string expression.

Return types

Returns a string expression.

Examples

The following example shows how to use `RTRIM` inside a query.

```
SELECT RTRIM("  abc") AS r1, RTRIM("abc") AS r2, RTRIM("abc   ") AS r3
```

Here is the result set.

```
[{"r1": "   abc", "r2": "abc", "r3": "abc"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

STARTSWITH (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean indicating whether the first string expression starts with the second.

Syntax

```
STARTSWITH(<str_expr1>, <str_expr2> [, <bool_expr>])
```

Arguments

str_expr1
Is a string expression.

str_expr2
Is a string expression to be compared to the beginning of *str_expr1*.

bool_expr Optional value for ignoring case. When set to true, STARTSWITH will do a case-insensitive search. When unspecified, this value is false.

Return types

Returns a Boolean expression.

Examples

The following example checks if the string "abc" begins with "b" and "A".

```
SELECT STARTSWITH("abc", "b", false) AS s1, STARTSWITH("abc", "A", false) AS s2, STARTSWITH("abc", "A", true)
AS s3
```

Here is the result set.

```
[
    {
        "s1": false,
        "s2": false,
        "s3": true
    }
]
```

Remarks

This system function will benefit from a range index.

Next steps

- String functions Azure Cosmos DB

- System functions Azure Cosmos DB

STRINGEQUALS (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean indicating whether the first string expression matches the second.

Syntax

```
STRINGEQUALS(<str_expr1>, <str_expr2> [, <bool_expr>])
```

Arguments

str_expr1
Is the first string expression to compare.

str_expr2
Is the second string expression to compare.

bool_expr Optional value for ignoring case. When set to true, StringEquals will do a case-insensitive search. When unspecified, this value is false.

Return types

Returns a Boolean expression.

Examples

The following example checks if "abc" matches "abc" and if "abc" matches "ABC".

```
SELECT STRINGEQUALS("abc", "abc", false) AS c1, STRINGEQUALS("abc", "ABC", false) AS c2,  STRINGEQUALS("abc",
"ABC", true) AS c3
```

Here is the result set.

```
[
    {
        "c1": true,
        "c2": false,
        "c3": true
    }
]
```

Remarks

This system function will benefit from a range index.

Next steps

- String functions Azure Cosmos DB

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

StringToArray (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns expression translated to an Array. If expression cannot be translated, returns undefined.

Syntax

```
StringToArray(<str_expr>)
```

Arguments

str_expr
Is a string expression to be parsed as a JSON Array expression.

Return types

Returns an array expression or undefined.

Remarks

Nested string values must be written with double quotes to be valid JSON. For details on the JSON format, see json.org. This system function will not utilize the index.

Examples

The following example shows how `StringToArray` behaves across different types.

The following are examples with valid input.

```
SELECT
    StringToArray('[]') AS a1,
    StringToArray("[1,2,3]") AS a2,
    StringToArray("[\"str\",2,3]") AS a3,
    StringToArray('[["5","6","7"],["8"],["9"]]') AS a4,
    StringToArray('[1,2,3, "[4,5,6]",[7,8]]') AS a5
```

Here is the result set.

```
[{"a1": [], "a2": [1,2,3], "a3": ["str",2,3], "a4": [["5","6","7"],["8"],["9"]], "a5": [1,2,3,"[4,5,6]",
[7,8]]}]
```

The following is an example of invalid input.

Single quotes within the array are not valid JSON. Even though they are valid within a query, they will not parse to valid arrays. Strings within the array string must either be escaped "[\"\"]" or the surrounding quote must be single '[""]'.

```
SELECT
    StringToArray("['5','6','7']")
```

Here is the result set.

```
[{}]
```

The following are examples of invalid input.

The expression passed will be parsed as a JSON array; the following do not evaluate to type array and thus return undefined.

```
SELECT
    StringToArray("["),
    StringToArray("1"),
    StringToArray(NaN),
    StringToArray(false),
    StringToArray(undefined)
```

Here is the result set.

```
[{}]
```

StringToBoolean (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns expression translated to a Boolean. If expression cannot be translated, returns undefined.

Syntax

```
StringToBoolean(<str_expr>)
```

Arguments

str_expr
Is a string expression to be parsed as a Boolean expression.

Return types

Returns a Boolean expression or undefined.

Examples

The following example shows how `StringToBoolean` behaves across different types.

The following are examples with valid input.

Whitespace is allowed only before or after "true"/"false".

```
SELECT
    StringToBoolean("true") AS b1,
    StringToBoolean("    false") AS b2,
    StringToBoolean("false    ") AS b3
```

Here is the result set.

```
[{"b1": true, "b2": false, "b3": false}]
```

The following are examples with invalid input.

Booleans are case sensitive and must be written with all lowercase characters i.e. "true" and "false".

```
SELECT
    StringToBoolean("TRUE"),
    StringToBoolean("False")
```

Here is the result set.

```
[{}]
```

The expression passed will be parsed as a Boolean expression; these inputs do not evaluate to type Boolean and thus return undefined.

```
SELECT
    StringToBoolean("null"),
    StringToBoolean(undefined),
    StringToBoolean(NaN),
    StringToBoolean(false),
    StringToBoolean(true)
```

Here is the result set.

```
[{}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

StringToNull (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns expression translated to null. If expression cannot be translated, returns undefined.

Syntax

```
StringToNull(<str_expr>)
```

Arguments

str_expr
Is a string expression to be parsed as a null expression.

Return types

Returns a null expression or undefined.

Examples

The following example shows how `StringToNull` behaves across different types.

The following are examples with valid input.

Whitespace is allowed only before or after "null".

```
SELECT
    StringToNull("null") AS n1,
    StringToNull("  null ") AS n2,
    IS_NULL(StringToNull("null   ")) AS n3
```

Here is the result set.

```
[{"n1": null, "n2": null, "n3": true}]
```

The following are examples with invalid input.

Null is case sensitive and must be written with all lowercase characters i.e. "null".

```
SELECT
    StringToNull("NULL"),
    StringToNull("Null")
```

Here is the result set.

```
[{}]
```

The expression passed will be parsed as a null expression; these inputs do not evaluate to type null and thus return undefined.

```
SELECT
    StringToNull("true"),
    StringToNull(false),
    StringToNull(undefined),
    StringToNull(NaN)
```

Here is the result set.

```
[{}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

StringToNumber (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns expression translated to a Number. If expression cannot be translated, returns undefined.

Syntax

```
StringToNumber(<str_expr>)
```

Arguments

str_expr
Is a string expression to be parsed as a JSON Number expression. Numbers in JSON must be an integer or a floating point. For details on the JSON format, see json.org

Return types

Returns a Number expression or undefined.

Examples

The following example shows how `StringToNumber` behaves across different types.

Whitespace is allowed only before or after the Number.

```
SELECT
    StringToNumber("1.000000") AS num1,
    StringToNumber("3.14") AS num2,
    StringToNumber("   60   ") AS num3,
    StringToNumber("-1.79769e+308") AS num4
```

Here is the result set.

```
{{"num1": 1, "num2": 3.14, "num3": 60, "num4": -1.79769e+308}}
```

In JSON a valid Number must be either be an integer or a floating point number.

```
SELECT
    StringToNumber("0xF")
```

Here is the result set.

```
{{}}
```

The expression passed will be parsed as a Number expression; these inputs do not evaluate to type Number and thus return undefined.

```
SELECT
    StringToNumber("99     54"),
    StringToNumber(undefined),
    StringToNumber("false"),
    StringToNumber(false),
    StringToNumber(" "),
    StringToNumber(NaN)
```

Here is the result set.

```
{{}}
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

StringToObject (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns expression translated to an Object. If expression cannot be translated, returns undefined.

Syntax

```
StringToObject(<str_expr>)
```

Arguments

str_expr
Is a string expression to be parsed as a JSON object expression. Note that nested string values must be written with double quotes to be valid. For details on the JSON format, see json.org

Return types

Returns an object expression or undefined.

Examples

The following example shows how `StringToObject` behaves across different types.

The following are examples with valid input.

```
SELECT
    StringToObject("{}") AS obj1,
    StringToObject('{"A":[1,2,3]}') AS obj2,
    StringToObject('{"B":[{"b1":[5,6,7]},{"b2":8},{"b3":9}]}') AS obj3,
    StringToObject("{\"C\":[{\"c1\":[5,6,7]},{\"c2\":8},{\"c3\":9}]}") AS obj4
```

Here is the result set.

```
[{"obj1": {},
  "obj2": {"A": [1,2,3]},
  "obj3": {"B":[{"b1":[5,6,7]},{"b2":8},{"b3":9}]},
  "obj4": {"C":[{"c1":[5,6,7]},{"c2":8},{"c3":9}]}}]
```

The following are examples with invalid input. Even though they are valid within a query, they will not parse to valid objects. Strings within the string of object must either be escaped "{\"a\":\"str\"}" or the surrounding quote must be single '{"a": "str"}'.

Single quotes surrounding property names are not valid JSON.

```
SELECT
    StringToObject("{'a':[1,2,3]}")
```

Here is the result set.

```
[{}]
```

Property names without surrounding quotes are not valid JSON.

```
SELECT
    StringToObject("{a:[1,2,3]}")
```

Here is the result set.

```
[{}]
```

The following are examples with invalid input.

The expression passed will be parsed as a JSON object; these inputs do not evaluate to type object and thus return undefined.

```
SELECT
    StringToObject("}"),
    StringToObject("{"),
    StringToObject("1"),
    StringToObject(NaN),
    StringToObject(false),
    StringToObject(undefined)
```

Here is the result set.

```
[{}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB

SUBSTRING (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns part of a string expression starting at the specified character zero-based position and continues to the specified length, or to the end of the string.

Syntax

```
SUBSTRING(<str_expr>, <num_expr1>, <num_expr2>)
```

Arguments

str_expr
Is a string expression.

num_expr1
Is a numeric expression to denote the start character. A value of 0 is the first character of *str_expr*.

num_expr2
Is a numeric expression to denote the maximum number of characters of *str_expr* to be returned. A value of 0 or less results in empty string.

Return types

Returns a string expression.

Examples

The following example returns the substring of "abc" starting at 1 and for a length of 1 character.

```
SELECT SUBSTRING("abc", 1, 1) AS substring
```

Here is the result set.

```
[{"substring": "b"}]
```

Remarks

This system function will benefit from a range index if the starting position is `0`.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

ToString (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string representation of scalar expression.

Syntax

```
ToString(<expr>)
```

Arguments

expr
Is any scalar expression.

Return types

Returns a string expression.

Examples

The following example shows how `ToString` behaves across different types.

```
SELECT
    ToString(1.0000) AS str1,
    ToString("Hello World") AS str2,
    ToString(NaN) AS str3,
    ToString(Infinity) AS str4,
    ToString(IS_STRING(ToString(undefined))) AS str5,
    ToString(0.1234) AS str6,
    ToString(false) AS str7,
    ToString(undefined) AS str8
```

Here is the result set.

```
[{"str1": "1", "str2": "Hello World", "str3": "NaN", "str4": "Infinity", "str5": "false", "str6": "0.1234",
"str7": "false"}]
```

Given the following input:

```
{"Products":[{"ProductID":1,"Weight":4,"WeightUnits":"lb"},{"ProductID":2,"Weight":32,"WeightUnits":"kg"},
{"ProductID":3,"Weight":400,"WeightUnits":"g"},{"ProductID":4,"Weight":8999,"WeightUnits":"mg"}]}
```

The following example shows how `ToString` can be used with other string functions like `CONCAT`.

```
SELECT
CONCAT(ToString(p.Weight), p.WeightUnits)
FROM p in c.Products
```

Here is the result set.

```
[{"$1":"4lb" },
{"$1":"32kg"},
{"$1":"400g" },
{"$1":"8999mg" }]
```

Given the following input.

```
{"id":"08259","description":"Cereals ready-to-eat, KELLOGG, KELLOGG'S CRISPIX","nutrients":
[{"id":"305","description":"Caffeine","units":"mg"},{"id":"306","description":"Cholesterol,
HDL","nutritionValue":30,"units":"mg"},{"id":"307","description":"Sodium,
NA","nutritionValue":612,"units":"mg"},{"id":"308","description":"Protein,
ABP","nutritionValue":60,"units":"mg"},{"id":"309","description":"Zinc,
ZN","nutritionValue":null,"units":"mg"}]}
```

The following example shows how `ToString` can be used with other string functions like `REPLACE`.

```
SELECT
    n.id AS nutrientID,
    REPLACE(ToString(n.nutritionValue), "6", "9") AS nutritionVal
FROM food
JOIN n IN food.nutrients
```

Here is the result set.

```
[{"nutrientID":"305"},
{"nutrientID":"306","nutritionVal":"30"},
{"nutrientID":"307","nutritionVal":"912"},
{"nutrientID":"308","nutritionVal":"90"},
{"nutrientID":"309","nutritionVal":"null"}]
```

Remarks

This system function will not utilize the index.

Next steps

TRIM (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string expression after it removes leading and trailing blanks.

Syntax

```
TRIM(<str_expr>)
```

Arguments

str_expr
Is a string expression.

Return types

Returns a string expression.

Examples

The following example shows how to use `TRIM` inside a query.

```
SELECT TRIM("   abc") AS t1, TRIM("   abc   ") AS t2, TRIM("abc   ") AS t3, TRIM("abc") AS t4
```

Here is the result set.

```
[{"t1": "abc", "t2": "abc", "t3": "abc", "t4": "abc"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

UPPER (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a string expression after converting lowercase character data to uppercase.

The UPPER system function does not utilize the index. If you plan to do frequent case insensitive comparisons, the UPPER system function may consume a significant amount of RU's. If this is the case, instead of using the UPPER system function to normalize data each time for comparisons, you can normalize the casing upon insertion. Then a query such as SELECT * FROM c WHERE UPPER(c.name) = 'BOB' simply becomes SELECT * FROM c WHERE c.name = 'BOB'.

Syntax

```
UPPER(<str_expr>)
```

Arguments

str_expr
Is a string expression.

Return types

Returns a string expression.

Examples

The following example shows how to use `UPPER` in a query

```
SELECT UPPER("Abc") AS upper
```

Here is the result set.

```
[{"upper": "ABC"}]
```

Remarks

This system function will not utilize the index.

Next steps

- String functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

Type checking functions (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The type-checking functions let you check the type of an expression within a SQL query. You can use type-checking functions to determine the types of properties within items on the fly, when they're variable or unknown.

Functions

Here's a table of supported built-in type-checking functions:

The following functions support type checking against input values, and each return a Boolean value.

- IS_ARRAY
- IS_BOOL
- IS_DEFINED
- IS_NULL
- IS_NUMBER
- IS_OBJECT
- IS_PRIMITIVE
- IS_STRING

Next steps

- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB
- User Defined Functions
- Aggregates

IS_ARRAY (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is an array.

Syntax

```
IS_ARRAY(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array, and undefined types using the `IS_ARRAY` function.

```
SELECT
 IS_ARRAY(true) AS isArray1,
 IS_ARRAY(1) AS isArray2,
 IS_ARRAY("value") AS isArray3,
 IS_ARRAY(null) AS isArray4,
 IS_ARRAY({prop: "value"}) AS isArray5,
 IS_ARRAY([1, 2, 3]) AS isArray6,
 IS_ARRAY({prop: "value"}.prop2) AS isArray7
```

Here is the result set.

```
[{"isArray1":false,"isArray2":false,"isArray3":false,"isArray4":false,"isArray5":false,"isArray6":true,"isArra
y7":false}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

IS_BOOL (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is a Boolean.

Syntax

```
IS_BOOL(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array, and undefined types using the `IS_BOOL` function.

```
SELECT
    IS_BOOL(true) AS isBool1,
    IS_BOOL(1) AS isBool2,
    IS_BOOL("value") AS isBool3,
    IS_BOOL(null) AS isBool4,
    IS_BOOL({prop: "value"}) AS isBool5,
    IS_BOOL([1, 2, 3]) AS isBool6,
    IS_BOOL({prop: "value"}.prop2) AS isBool7
```

Here is the result set.

```
[{"isBool1":true,"isBool2":false,"isBool3":false,"isBool4":false,"isBool5":false,"isBool6":false,"isBool7":fal
se}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

IS_DEFINED (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean indicating if the property has been assigned a value.

Syntax

```
IS_DEFINED(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks for the presence of a property within the specified JSON document. The first returns true since "a" is present, but the second returns false since "b" is absent.

```
SELECT IS_DEFINED({ "a" : 5 }.a) AS isDefined1, IS_DEFINED({ "a" : 5 }.b) AS isDefined2
```

Here is the result set.

```
[{"isDefined1":true,"isDefined2":false}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

IS_NULL (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is null.

Syntax

```
IS_NULL(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array, and undefined types using the `IS_NULL` function.

```
SELECT
    IS_NULL(true) AS isNull1,
    IS_NULL(1) AS isNull2,
    IS_NULL("value") AS isNull3,
    IS_NULL(null) AS isNull4,
    IS_NULL({prop: "value"}) AS isNull5,
    IS_NULL([1, 2, 3]) AS isNull6,
    IS_NULL({prop: "value"}.prop2) AS isNull7
```

Here is the result set.

```
[{"isNull1":false,"isNull2":false,"isNull3":false,"isNull4":true,"isNull5":false,"isNull6":false,"isNull7":fal
se}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

IS_NUMBER (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is a number.

Syntax

```
IS_NUMBER(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array, and undefined types using the `IS_NUMBER` function.

```
SELECT
    IS_NUMBER(true) AS isNum1,
    IS_NUMBER(1) AS isNum2,
    IS_NUMBER("value") AS isNum3,
    IS_NUMBER(null) AS isNum4,
    IS_NUMBER({prop: "value"}) AS isNum5,
    IS_NUMBER([1, 2, 3]) AS isNum6,
    IS_NUMBER({prop: "value"}.prop2) AS isNum7
```

Here is the result set.

```
[{"isNum1":false,"isNum2":true,"isNum3":false,"isNum4":false,"isNum5":false,"isNum6":false,"isNum7":false}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB
- Introduction to Azure Cosmos DB

IS_OBJECT (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is a JSON object.

Syntax

```
IS_OBJECT(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array, and undefined types using the `IS_OBJECT` function.

```
SELECT
    IS_OBJECT(true) AS isObj1,
    IS_OBJECT(1) AS isObj2,
    IS_OBJECT("value") AS isObj3,
    IS_OBJECT(null) AS isObj4,
    IS_OBJECT({prop: "value"}) AS isObj5,
    IS_OBJECT([1, 2, 3]) AS isObj6,
    IS_OBJECT({prop: "value"}.prop2) AS isObj7
```

Here is the result set.

```
[{"isObj1":false,"isObj2":false,"isObj3":false,"isObj4":false,"isObj5":true,"isObj6":false,"isObj7":false}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB

IS_PRIMITIVE (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is a primitive (string, Boolean, numeric, or null).

Syntax

```
IS_PRIMITIVE(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array and undefined types using the `IS_PRIMITIVE` function.

```
SELECT
           IS_PRIMITIVE(true) AS isPrim1,
           IS_PRIMITIVE(1) AS isPrim2,
           IS_PRIMITIVE("value") AS isPrim3,
           IS_PRIMITIVE(null) AS isPrim4,
           IS_PRIMITIVE({prop: "value"}) AS isPrim5,
           IS_PRIMITIVE([1, 2, 3]) AS isPrim6,
           IS_PRIMITIVE({prop: "value"}.prop2) AS isPrim7
```

Here is the result set.

```
[{"isPrim1": true, "isPrim2": true, "isPrim3": true, "isPrim4": true, "isPrim5": false, "isPrim6": false,
"isPrim7": false}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB
- System functions Azure Cosmos DB

IS_STRING (Azure Cosmos DB)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Returns a Boolean value indicating if the type of the specified expression is a string.

Syntax

```
IS_STRING(<expr>)
```

Arguments

expr
Is any expression.

Return types

Returns a Boolean expression.

Examples

The following example checks objects of JSON Boolean, number, string, null, object, array, and undefined types using the `IS_STRING` function.

```
SELECT
       IS_STRING(true) AS isStr1,
       IS_STRING(1) AS isStr2,
       IS_STRING("value") AS isStr3,
       IS_STRING(null) AS isStr4,
       IS_STRING({prop: "value"}) AS isStr5,
       IS_STRING([1, 2, 3]) AS isStr6,
       IS_STRING({prop: "value"}.prop2) AS isStr7
```

Here is the result set.

```
[{"isStr1":false,"isStr2":false,"isStr3":true,"isStr4":false,"isStr5":false,"isStr6":false,"isStr7":false}]
```

Remarks

This system function will benefit from a range index.

Next steps

- Type checking functions Azure Cosmos DB

Geospatial and GeoJSON location data in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This article is an introduction to the geospatial functionality in Azure Cosmos DB. Currently storing and accessing geospatial data is supported by Azure Cosmos DB SQL API accounts only. After reading our documentation on geospatial indexing you will be able to answer the following questions:

- How do I store spatial data in Azure Cosmos DB?
- How can I query geospatial data in Azure Cosmos DB in SQL and LINQ?
- How do I enable or disable spatial indexing in Azure Cosmos DB?

Spatial Data Use Cases

Geospatial data often involve proximity queries, for example, "find all coffee shops near my current location". Common use cases are:

- Geolocation Analytics, driving specific located marketing initiatives.
- Location based personalization, for multiple industries like Retail and Healthcare.
- Logistics enhancement, for transport optimization.
- Risk Analysis, especially for insurance and finance companies.
- Situational awareness, for alerts and notifications.

Introduction to spatial data

Spatial data describes the position and shape of objects in space. In most applications, these correspond to objects on the earth and geospatial data. Spatial data can be used to represent the location of a person, a place of interest, or the boundary of a city, or a lake.

Azure Cosmos DB's SQL API supports two spatial data types: the **geometry** data type and the **geography** data type.

- The **geometry** type represents data in a Euclidean (flat) coordinate system
- The **geography** type represents data in a round-earth coordinate system.

Supported data types

Azure Cosmos DB supports indexing and querying of geospatial point data that's represented using the GeoJSON specification. GeoJSON data structures are always valid JSON objects, so they can be stored and queried using Azure Cosmos DB without any specialized tools or libraries.

Azure Cosmos DB supports the following spatial data types:

- Point
- LineString
- Polygon
- MultiPolygon

Points

A **Point** denotes a single position in space. In geospatial data, a Point represents the exact location, which could be a street address of a grocery store, a kiosk, an automobile, or a city. A point is represented in GeoJSON (and Azure Cosmos DB) using its coordinate pair or longitude and latitude.

Here's an example JSON for a point:

Points in Azure Cosmos DB

```
{
    "type":"Point",
    "coordinates":[ 31.9, -4.8 ]
}
```

Spatial data types can be embedded in an Azure Cosmos DB document as shown in this example of a user profile containing location data:

Use Profile with Location stored in Azure Cosmos DB

```
{
    "id":"cosmosdb-profile",
    "screen_name":"@CosmosDB",
    "city":"Redmond",
    "topics":[ "global", "distributed" ],
    "location":{
        "type":"Point",
        "coordinates":[ 31.9, -4.8 ]
    }
}
```

Points in a geometry coordinate system

For the **geometry** data type, GeoJSON specification specifies the horizontal axis first and the vertical axis second.

Points in a geography coordinate system

For the **geography** data type, GeoJSON specification specifies longitude first and latitude second. Like in other mapping applications, longitude and latitude are angles and represented in terms of degrees. Longitude values are measured from the Prime Meridian and are between -180 degrees and 180.0 degrees, and latitude values are measured from the equator and are between -90.0 degrees and 90.0 degrees.

Azure Cosmos DB interprets coordinates as represented per the WGS-84 reference system. See below for more details about coordinate reference systems.

LineStrings

LineStrings represent a series of two or more points in space and the line segments that connect them. In geospatial data, LineStrings are commonly used to represent highways or rivers.

LineStrings in GeoJSON

```
    "type":"LineString",
    "coordinates":[ [
        [ 31.8, -5 ],
        [ 31.8, -4.7 ]
    ] ]
```

Polygons

A **Polygon** is a boundary of connected points that forms a closed LineString. Polygons are commonly used to represent natural formations like lakes or political jurisdictions like cities and states. Here's an example of a Polygon in Azure Cosmos DB:

Polygons in GeoJSON

```
{
    "type":"Polygon",
    "coordinates":[ [
        [ 31.8, -5 ],
        [ 31.8, -4.7 ],
        [ 32, -4.7 ],
        [ 32, -5 ],
        [ 31.8, -5 ]
    ] ]
}
```

> **NOTE**
>
> The GeoJSON specification requires that for valid Polygons, the last coordinate pair provided should be the same as the first, to create a closed shape.
>
> Points within a Polygon must be specified in counter-clockwise order. A Polygon specified in clockwise order represents the inverse of the region within it.

MultiPolygons

A **MultiPolygon** is an array of zero or more Polygons. **MultiPolygons** cannot overlap sides or have any common area. They may touch at one or more points.

MultiPolygons in GeoJSON

```
{
    "type":"MultiPolygon",
    "coordinates":[[[
        [52.0, 12.0],
        [53.0, 12.0],
        [53.0, 13.0],
        [52.0, 13.0],
        [52.0, 12.0]
        ]],
        [[
        [50.0, 0.0],
        [51.0, 0.0],
        [51.0, 5.0],
        [50.0, 5.0],
        [50.0, 0.0]
        ]]]
}
```

Coordinate reference systems

Since the shape of the earth is irregular, coordinates of geography geospatial data are represented in many coordinate reference systems (CRS), each with their own frames of reference and units of measurement. For example, the "National Grid of Britain" is a reference system is accurate for the United Kingdom, but not outside it.

The most popular CRS in use today is the World Geodetic System WGS-84. GPS devices, and many mapping services including Google Maps and Bing Maps APIs use WGS-84. Azure Cosmos DB supports indexing and querying of geography geospatial data using the WGS-84 CRS only.

Creating documents with spatial data

When you create documents that contain GeoJSON values, they are automatically indexed with a spatial index in

accordance to the indexing policy of the container. If you're working with an Azure Cosmos DB SDK in a dynamically typed language like Python or Node.js, you must create valid GeoJSON.

Create Document with Geospatial data in Node.js

```
var userProfileDocument = {
    "id":"cosmosdb",
    "location":{
        "type":"Point",
        "coordinates":[ -122.12, 47.66 ]
    }
};

client.createDocument(`dbs/${databaseName}/colls/${collectionName}`, userProfileDocument, (err, created) => {
    // additional code within the callback
});
```

If you're working with the SQL APIs, you can use the `Point`, `LineString`, `Polygon`, and `MultiPolygon` classes within the `Microsoft.Azure.Cosmos.Spatial` namespace to embed location information within your application objects. These classes help simplify the serialization and deserialization of spatial data into GeoJSON.

Create Document with Geospatial data in .NET

```
using Microsoft.Azure.Cosmos.Spatial;

public class UserProfile
{
    [JsonProperty("id")]
    public string id { get; set; }

    [JsonProperty("location")]
    public Point Location { get; set; }

    // More properties
}

await container.CreateItemAsync( new UserProfile
    {
        id = "cosmosdb",
        Location = new Point (-122.12, 47.66)
    });
```

If you don't have the latitude and longitude information, but have the physical addresses or location name like city or country/region, you can look up the actual coordinates by using a geocoding service like Bing Maps REST Services. Learn more about Bing Maps geocoding here.

Querying geospatial data with Azure Cosmos DB

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

This article will cover how to query geospatial data in Azure Cosmos DB using SQL and LINQ. Currently storing and accessing geospatial data is supported by Azure Cosmos DB SQL API accounts only. Azure Cosmos DB supports the following Open Geospatial Consortium (OGC) built-in functions for geospatial querying. For more information on the complete set of built-in functions in the SQL language, see Query System Functions in Azure Cosmos DB.

Spatial SQL built-in functions

Here is a list of geospatial system functions useful for querying in Azure Cosmos DB:

USAGE	DESCRIPTION
ST_DISTANCE (spatial_expr, spatial_expr)	Returns the distance between the two GeoJSON Point, Polygon, or LineString expressions.
ST_WITHIN (spatial_expr, spatial_expr)	Returns a Boolean expression indicating whether the first GeoJSON object (Point, Polygon, or LineString) is within the second GeoJSON object (Point, Polygon, or LineString).
ST_INTERSECTS (spatial_expr, spatial_expr)	Returns a Boolean expression indicating whether the two specified GeoJSON objects (Point, Polygon, or LineString) intersect.
ST_ISVALID	Returns a Boolean value indicating whether the specified GeoJSON Point, Polygon, or LineString expression is valid.
ST_ISVALIDDETAILED	Returns a JSON value containing a Boolean value if the specified GeoJSON Point, Polygon, or LineString expression is valid. If invalid, it returns the reason as a string value.

Spatial functions can be used to perform proximity queries against spatial data. For example, here's a query that returns all family documents that are within 30 km of the specified location using the `ST_DISTANCE` built-in function.

Query

```
SELECT f.id
FROM Families f
WHERE ST_DISTANCE(f.location, {"type": "Point", "coordinates":[31.9, -4.8]}) < 30000
```

Results

```
[{
  "id": "WakefieldFamily"
}]
```

If you include spatial indexing in your indexing policy, then "distance queries" will be served efficiently through the

index. For more information on spatial indexing, see geospatial indexing. If you don't have a spatial index for the specified paths, the query will do a scan of the container.

`ST_WITHIN` can be used to check if a point lies within a Polygon. Commonly Polygons are used to represent boundaries like zip codes, state boundaries, or natural formations. Again if you include spatial indexing in your indexing policy, then "within" queries will be served efficiently through the index.

Polygon arguments in `ST_WITHIN` can contain only a single ring, that is, the Polygons must not contain holes in them.

Query

```
SELECT *
FROM Families f
WHERE ST_WITHIN(f.location, {
    "type":"Polygon",
    "coordinates": [[[31.8, -5], [32, -5], [32, -4.7], [31.8, -4.7], [31.8, -5]]]
})
```

Results

```
[{
  "id": "WakefieldFamily",
}]
```

> **NOTE**
>
> Similar to how mismatched types work in Azure Cosmos DB query, if the location value specified in either argument is malformed or invalid, then it evaluates to **undefined** and the evaluated document to be skipped from the query results. If your query returns no results, run `ST_ISVALIDDETAILED` to debug why the spatial type is invalid.

Azure Cosmos DB also supports performing inverse queries, that is, you can index polygons or lines in Azure Cosmos DB, then query for the areas that contain a specified point. This pattern is commonly used in logistics to identify, for example, when a truck enters or leaves a designated area.

Query

```
SELECT *
FROM Areas a
WHERE ST_WITHIN({"type": "Point", "coordinates":[31.9, -4.8]}, a.location)
```

Results

```
[{
  "id": "MyDesignatedLocation",
  "location": {
    "type":"Polygon",
    "coordinates": [[[31.8, -5], [32, -5], [32, -4.7], [31.8, -4.7], [31.8, -5]]]
  }
}]
```

`ST_ISVALID` and `ST_ISVALIDDETAILED` can be used to check if a spatial object is valid. For example, the following query checks the validity of a point with an out of range latitude value (-132.8). `ST_ISVALID` returns just a Boolean value, and `ST_ISVALIDDETAILED` returns the Boolean and a string containing the reason why it is considered invalid.

Query

```
SELECT ST_ISVALID({ "type": "Point", "coordinates": [31.9, -132.8] })
```

Results

```
[{
  "$1": false
}]
```

These functions can also be used to validate Polygons. For example, here we use `ST_ISVALIDDETAILED` to validate a Polygon that is not closed.

Query

```
SELECT ST_ISVALIDDETAILED({ "type": "Polygon", "coordinates": [[
    [ 31.8, -5 ], [ 31.8, -4.7 ], [ 32, -4.7 ], [ 32, -5 ]
    ]]})
```

Results

```
[{
   "$1": {
        "valid": false,
        "reason": "The Polygon input is not valid because the start and end points of the ring number 1
are not the same. Each ring of a Polygon must have the same start and end points."
      }
}]
```

LINQ querying in the .NET SDK

The SQL .NET SDK also providers stub methods `Distance()` and `Within()` for use within LINQ expressions. The SQL LINQ provider translates this method calls to the equivalent SQL built-in function calls (ST_DISTANCE and ST_WITHIN respectively).

Here's an example of a LINQ query that finds all documents in the Azure Cosmos container whose `location` value is within a radius of 30 km of the specified point using LINQ.

LINQ query for Distance

```
foreach (UserProfile user in container.GetItemLinqQueryable<UserProfile>(allowSynchronousQueryExecution:
true)
    .Where(u => u.ProfileType == "Public" && u.Location.Distance(new Point(32.33, -4.66)) < 30000))
{
    Console.WriteLine("\t" + user);
}
```

Similarly, here's a query for finding all the documents whose `location` is within the specified box/Polygon.

LINQ query for Within

```
    Polygon rectangularArea = new Polygon(
        new[]
        {
            new LinearRing(new [] {
                new Position(31.8, -5),
                new Position(32, -5),
                new Position(32, -4.7),
                new Position(31.8, -4.7),
                new Position(31.8, -5)
            })
        });

    foreach (UserProfile user in container.GetItemLinqQueryable<UserProfile>(allowSynchronousQueryExecution:
true)
         .Where(a => a.Location.Within(rectangularArea)))
    {
        Console.WriteLine("\t" + user);
    }
```

Index geospatial data with Azure Cosmos DB

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

We designed Azure Cosmos DB's database engine to be truly schema agnostic and provide first class support for JSON. The write optimized database engine of Azure Cosmos DB natively understands spatial data represented in the GeoJSON standard.

In a nutshell, the geometry is projected from geodetic coordinates onto a 2D plane then divided progressively into cells using a **quadtree**. These cells are mapped to 1D based on the location of the cell within a **Hilbert space filling curve**, which preserves locality of points. Additionally when location data is indexed, it goes through a process known as **tessellation**, that is, all the cells that intersect a location are identified and stored as keys in the Azure Cosmos DB index. At query time, arguments like points and Polygons are also tessellated to extract the relevant cell ID ranges, then used to retrieve data from the index.

If you specify an indexing policy that includes a spatial index for `/*` (all paths), then all data found within the container is indexed for efficient spatial queries.

> **NOTE**
>
> Azure Cosmos DB supports indexing of Points, LineStrings, Polygons, and MultiPolygons. If you index any one of these types, we will automatically index all other types. In other words, if you index Polygons, we'll also index Points, LineStrings, and MultiPolygons. Indexing a new spatial type does not affect the write RU charge or index size unless you have valid GeoJSON data of that type.

Modifying geospatial configuration

In your container, the **Geospatial Configuration** specifies how the spatial data will be indexed. Specify one **Geospatial Configuration** per container: geography or geometry.

You can toggle between the **geography** and **geometry** spatial type in the Azure portal. It's important that you create a valid spatial geometry indexing policy with a bounding box before switching to the geometry spatial type.

Here's how to set the **Geospatial Configuration** in **Data Explorer** within the Azure portal:

You can also modify the `geospatialConfig` in the .NET SDK to adjust the **Geospatial Configuration**:

If not specified, the `geospatialConfig` will default to the geography data type. When you modify the `geospatialConfig`, all existing geospatial data in the container will be reindexed.

Here is an example for modifying the geospatial data type to `geometry` by setting the `geospatialConfig` property and adding a **boundingBox**:

```
    //Retrieve the container's details
    ContainerResponse containerResponse = await client.GetContainer("db", "spatial").ReadContainerAsync();
    //Set GeospatialConfig to Geometry
    GeospatialConfig geospatialConfig = new GeospatialConfig(GeospatialType.Geometry);
    containerResponse.Resource.GeospatialConfig = geospatialConfig;
    // Add a spatial index including the required boundingBox
    SpatialPath spatialPath = new SpatialPath
            {
                Path = "/locations/*",
                BoundingBox = new BoundingBoxProperties(){
                    Xmin = 0,
                    Ymin = 0,
                    Xmax = 10,
                    Ymax = 10
                }
            };
    spatialPath.SpatialTypes.Add(SpatialType.Point);
    spatialPath.SpatialTypes.Add(SpatialType.LineString);
    spatialPath.SpatialTypes.Add(SpatialType.Polygon);
    spatialPath.SpatialTypes.Add(SpatialType.MultiPolygon);

    containerResponse.Resource.IndexingPolicy.SpatialIndexes.Add(spatialPath);

    // Update container with changes
    await client.GetContainer("db", "spatial").ReplaceContainerAsync(containerResponse.Resource);
```

Geography data indexing examples

The following JSON snippet shows an indexing policy with spatial indexing enabled for the **geography** data type. It is valid for spatial data with the geography data type and will index any GeoJSON Point, Polygon, MultiPolygon, or LineString found within documents for spatial querying. If you are modifying the indexing policy using the Azure portal, you can specify the following JSON for indexing policy to enable spatial indexing on your container:

Container indexing policy JSON with geography spatial indexing

```
{
    "automatic": true,
    "indexingMode": "Consistent",
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "spatialIndexes": [
        {
            "path": "/*",
            "types": [
                "Point",
                "Polygon",
                "MultiPolygon",
                "LineString"
            ]
        }
    ],
    "excludedPaths": []
}
```

> **NOTE**
> If the location GeoJSON value within the document is malformed or invalid, then it will not get indexed for spatial querying. You can validate location values using ST_ISVALID and ST_ISVALIDDETAILED.

You can also modify indexing policy using the Azure CLI, PowerShell, or any SDK.

Geometry data indexing examples

With the **geometry** data type, similar to the geography data type, you must specify relevant paths and types to index. In addition, you must also specify a `boundingBox` within the indexing policy to indicate the desired area to be indexed for that specific path. Each geospatial path requires its own `boundingBox`.

The bounding box consists of the following properties:

- **xmin**: the minimum indexed x coordinate
- **ymin**: the minimum indexed y coordinate
- **xmax**: the maximum indexed x coordinate
- **ymax**: the maximum indexed y coordinate

A bounding box is required because geometric data occupies a plane that can be infinite. Spatial indexes, however, require a finite space. For the **geography** data type, the Earth is the boundary and you do not need to set a bounding box.

Create a bounding box that contains all (or most) of your data. Only operations computed on the objects that are entirely inside the bounding box will be able to utilize the spatial index. Making the bounding box larger than necessary will negatively impact query performance.

Here is an example indexing policy that indexes **geometry** data with **geospatialConfig** set to `geometry`:

```
{
    "indexingMode": "consistent",
    "automatic": true,
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "excludedPaths": [
        {
            "path": "/\"_etag\"/?"
        }
    ],
    "spatialIndexes": [
        {
            "path": "/locations/*",
            "types": [
                "Point",
                "LineString",
                "Polygon",
                "MultiPolygon"
            ],
            "boundingBox": {
                "xmin": -10,
                "ymin": -20,
                "xmax": 10,
                "ymax": 20
            }
        }
    ]
}
```

The above indexing policy has a **boundingBox** of (-10, 10) for x coordinates and (-20, 20) for y coordinates. The container with the above indexing policy will index all Points, Polygons, MultiPolygons, and LineStrings that are entirely within this region.

> **NOTE**
>
> If you try to add an indexing policy with a **boundingBox** to a container with `geography` data type, it will fail. You should modify the container's **geospatialConfig** to be `geometry` before adding a **boundingBox**. You can add data and modify the remainder of your indexing policy (such as the paths and types) either before or after selecting the geospatial data type for the container.

Working with Dates in Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB delivers schema flexibility and rich indexing via a native JSON data model. All Azure Cosmos DB resources including databases, containers, documents, and stored procedures are modeled and stored as JSON documents. As a requirement for being portable, JSON (and Azure Cosmos DB) supports only a small set of basic types: String, Number, Boolean, Array, Object, and Null. However, JSON is flexible and allow developers and frameworks to represent more complex types using these primitives and composing them as objects or arrays.

In addition to the basic types, many applications need the DateTime type to represent dates and timestamps. This article describes how developers can store, retrieve, and query dates in Azure Cosmos DB using the .NET SDK.

Storing DateTimes

Azure Cosmos DB supports JSON types such as - string, number, boolean, null, array, object. It does not directly support a DateTime type. Currently, Azure Cosmos DB doesn't support localization of dates. So, you need to store DateTimes as strings. The recommended format for DateTime strings in Azure Cosmos DB is `yyyy-MM-ddTHH:mm:ss.fffffffZ` which follows the ISO 8601 UTC standard. It is recommended to store all dates in Azure Cosmos DB as UTC. Converting the date strings to this format will allow sorting dates lexicographically. If non-UTC dates are stored, the logic must be handled at the client-side. To convert a local DateTime to UTC, the offset must be known/stored as a property in the JSON and the client can use the offset to compute the UTC DateTime value.

Range queries with DateTime strings as filters are only supported if the DateTime strings are all in UTC and the same length. In Azure Cosmos DB, the GetCurrentDateTime system function will return the current UTC date and time ISO 8601 string value in the format: `yyyy-MM-ddTHH:mm:ss.fffffffZ`.

Most applications can use the default string representation for DateTime for the following reasons:

- Strings can be compared, and the relative ordering of the DateTime values is preserved when they are transformed to strings.
- This approach doesn't require any custom code or attributes for JSON conversion.
- The dates as stored in JSON are human readable.
- This approach can take advantage of Azure Cosmos DB's index for fast query performance.

For example, the following snippet stores an `Order` object containing two DateTime properties - `ShipDate` and `OrderDate` as a document using the .NET SDK:

```
public class Order
{
    [JsonProperty(PropertyName="id")]
    public string Id { get; set; }
    public DateTime OrderDate { get; set; }
    public DateTime ShipDate { get; set; }
    public double Total { get; set; }
}

await container.CreateItemAsync(
    new Order
    {
        Id = "09152014101",
        OrderDate = DateTime.UtcNow.AddDays(-30),
        ShipDate = DateTime.UtcNow.AddDays(-14),
        Total = 113.39
    });
```

This document is stored in Azure Cosmos DB as follows:

```
{
    "id": "09152014101",
    "OrderDate": "2014-09-15T23:14:25.7251173Z",
    "ShipDate": "2014-09-30T23:14:25.7251173Z",
    "Total": 113.39
}
```

Alternatively, you can store DateTimes as Unix timestamps, that is, as a number representing the number of elapsed seconds since January 1, 1970. Azure Cosmos DB's internal Timestamp (`_ts`) property follows this approach. You can use the UnixDateTimeConverter class to serialize DateTimes as numbers.

Querying DateTimes in LINQ

The SQL .NET SDK automatically supports querying data stored in Azure Cosmos DB via LINQ. For example, the following snippet shows a LINQ query that filters orders that were shipped in the last three days:

```
    IQueryable<Order> orders = container.GetItemLinqQueryable<Order>(allowSynchronousQueryExecution:
true).Where(o => o.ShipDate >= DateTime.UtcNow.AddDays(-3));
```

Translated to the following SQL statement and executed on Azure Cosmos DB:

```
SELECT * FROM root WHERE (root["ShipDate"] >= "2014-09-30T23:14:25.7251173Z")
```

You can learn more about Azure Cosmos DB's SQL query language and the LINQ provider at Querying Cosmos DB in LINQ.

Indexing DateTimes for range queries

Queries are common with DateTime values. To execute these queries efficiently, you must have an index defined on any properties in the query's filter.

You can learn more about how to configure indexing policies at Azure Cosmos DB Indexing Policies.

Parameterized queries in Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB supports queries with parameters expressed by the familiar @ notation. Parameterized SQL provides robust handling and escaping of user input, and prevents accidental exposure of data through SQL injection.

Examples

For example, you can write a query that takes `lastName` and `address.state` as parameters, and execute it for various values of `lastName` and `address.state` based on user input.

```
SELECT *
FROM Families f
WHERE f.lastName = @lastName AND f.address.state = @addressState
```

You can then send this request to Azure Cosmos DB as a parameterized JSON query like the following:

```
{
    "query": "SELECT * FROM Families f WHERE f.lastName = @lastName AND f.address.state = @addressState",
    "parameters": [
        {"name": "@lastName", "value": "Wakefield"},
        {"name": "@addressState", "value": "NY"},
    ]
}
```

The following example sets the TOP argument with a parameterized query:

```
{
    "query": "SELECT TOP @n * FROM Families",
    "parameters": [
        {"name": "@n", "value": 10},
    ]
}
```

Parameter values can be any valid JSON: strings, numbers, Booleans, null, even arrays or nested JSON. Since Azure Cosmos DB is schemaless, parameters aren't validated against any type.

Here are examples for parameterized queries in each Azure Cosmos DB SDK:

- .NET SDK
- Java
- Node.js
- Python

LINQ to SQL translation

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

The Azure Cosmos DB query provider performs a best effort mapping from a LINQ query into a Cosmos DB SQL query. If you want to get the SQL query that is translated from LINQ, use the `ToString()` method on the generated `IQueryable` object. The following description assumes a basic familiarity with LINQ. In addition to LINQ, Azure Cosmos DB also supports Entity Framework Core which works with SQL API.

The query provider type system supports only the JSON primitive types: numeric, Boolean, string, and null.

The query provider supports the following scalar expressions:

- Constant values, including constant values of the primitive data types at query evaluation time.
- Property/array index expressions that refer to the property of an object or an array element. For example:

```
family.Id;
family.children[0].familyName;
family.children[0].grade;
family.children[n].grade; //n is an int variable
```

- Arithmetic expressions, including common arithmetic expressions on numerical and Boolean values. For the complete list, see the Azure Cosmos DB SQL specification.

```
2 * family.children[0].grade;
x + y;
```

- String comparison expressions, which include comparing a string value to some constant string value.

```
mother.familyName == "Wakefield";
child.givenName == s; //s is a string variable
```

- Object/array creation expressions, which return an object of compound value type or anonymous type, or an array of such objects. You can nest these values.

```
new Parent { familyName = "Wakefield", givenName = "Robin" };
new { first = 1, second = 2 }; //an anonymous type with two fields
new int[] { 3, child.grade, 5 };
```

Using LINQ

You can create a LINQ query with `GetItemLinqQueryable`. This example shows LINQ query generation and asynchronous execution with a `FeedIterator`:

```
using (FeedIterator<Book> setIterator = container.GetItemLinqQueryable<Book>()
                      .Where(b => b.Title == "War and Peace")
                      .ToFeedIterator<Book>())
 {
     //Asynchronous query execution
     while (setIterator.HasMoreResults)
     {
         foreach(var item in await setIterator.ReadNextAsync()){
         {
             Console.WriteLine(item.cost);
         }
       }
     }
 }
```

Supported LINQ operators

The LINQ provider included with the SQL .NET SDK supports the following operators:

- **Select**: Projections translate to SELECT, including object construction.
- **Where**: Filters translate to WHERE, and support translation between `&&`, `||`, and `!` to the SQL operators
- **SelectMany**: Allows unwinding of arrays to the JOIN clause. Use to chain or nest expressions to filter on array elements.
- **OrderBy** and **OrderByDescending**: Translate to ORDER BY with ASC or DESC.
- **Count**, **Sum**, **Min**, **Max**, and **Average** operators for aggregation, and their async equivalents **CountAsync**, **SumAsync**, **MinAsync**, **MaxAsync**, and **AverageAsync**.
- **CompareTo**: Translates to range comparisons. Commonly used for strings, since they're not comparable in .NET.
- **Skip** and **Take**: Translates to OFFSET and LIMIT for limiting results from a query and doing pagination.
- **Math functions**: Supports translation from .NET `Abs`, `Acos`, `Asin`, `Atan`, `Ceiling`, `Cos`, `Exp`, `Floor`, `Log`, `Log10`, `Pow`, `Round`, `Sign`, `Sin`, `Sqrt`, `Tan`, and `Truncate` to the equivalent built-in mathematical functions.
- **String functions**: Supports translation from .NET `Concat`, `Contains`, `Count`, `EndsWith`, `IndexOf`, `Replace`, `Reverse`, `StartsWith`, `SubString`, `ToLower`, `ToUpper`, `TrimEnd`, and `TrimStart` to the equivalent built-in string functions.
- **Array functions**: Supports translation from .NET `Concat`, `Contains`, and `Count` to the equivalent built-in array functions.
- **Geospatial Extension functions**: Supports translation from stub methods `Distance`, `IsValid`, `IsValidDetailed`, and `Within` to the equivalent built-in geospatial functions.
- **User-Defined Function Extension function**: Supports translation from the stub method `UserDefinedFunctionProvider.Invoke` to the corresponding user-defined function.
- **Miscellaneous**: Supports translation of `Coalesce` and conditional operators. Can translate `Contains` to String CONTAINS, ARRAY_CONTAINS, or IN, depending on context.

Examples

The following examples illustrate how some of the standard LINQ query operators translate to queries in Azure Cosmos DB.

Select operator

The syntax is `input.Select(x => f(x))`, where `f` is a scalar expression. The `input`, in this case, would be an `IQueryable` object.

Select operator, example 1:

- **LINQ lambda expression**

```
input.Select(family => family.parents[0].familyName);
```

- SQL

```
SELECT VALUE f.parents[0].familyName
FROM Families f
```

Select operator, example 2:

- LINQ lambda expression

```
input.Select(family => family.children[0].grade + c); // c is an int variable
```

- SQL

```
SELECT VALUE f.children[0].grade + c
FROM Families f
```

Select operator, example 3:

- LINQ lambda expression

```
input.Select(family => new
{
    name = family.children[0].familyName,
    grade = family.children[0].grade + 3
});
```

- SQL

```
SELECT VALUE {"name":f.children[0].familyName,
              "grade": f.children[0].grade + 3 }
FROM Families f
```

SelectMany operator

The syntax is `input.SelectMany(x => f(x))`, where `f` is a scalar expression that returns a container type.

- LINQ lambda expression

```
input.SelectMany(family => family.children);
```

- SQL

```
SELECT VALUE child
FROM child IN Families.children
```

Where operator

The syntax is `input.Where(x => f(x))`, where `f` is a scalar expression, which returns a Boolean value.

Where operator, example 1:

- LINQ lambda expression

```
input.Where(family=> family.parents[0].familyName == "Wakefield");
```

- SQL

```
SELECT *
FROM Families f
WHERE f.parents[0].familyName = "Wakefield"
```

Where operator, example 2:

- LINQ lambda expression

```
input.Where(
    family => family.parents[0].familyName == "Wakefield" &&
    family.children[0].grade < 3);
```

- SQL

```
SELECT *
FROM Families f
WHERE f.parents[0].familyName = "Wakefield"
AND f.children[0].grade < 3
```

Composite SQL queries

You can compose the preceding operators to form more powerful queries. Since Cosmos DB supports nested containers, you can concatenate or nest the composition.

Concatenation

The syntax is `input(.|.SelectMany())(.Select()|.Where())*`. A concatenated query can start with an optional `SelectMany` query, followed by multiple `Select` or `Where` operators.

Concatenation, example 1:

- LINQ lambda expression

```
input.Select(family => family.parents[0])
    .Where(parent => parent.familyName == "Wakefield");
```

- SQL

```
SELECT *
FROM Families f
WHERE f.parents[0].familyName = "Wakefield"
```

Concatenation, example 2:

- LINQ lambda expression

```
input.Where(family => family.children[0].grade > 3)
    .Select(family => family.parents[0].familyName);
```

- SQL

```
SELECT VALUE f.parents[0].familyName
FROM Families f
WHERE f.children[0].grade > 3
```

Concatenation, example 3:

- LINQ lambda expression

```
input.Select(family => new { grade=family.children[0].grade}).
    Where(anon=> anon.grade < 3);
```

- SQL

```
SELECT *
FROM Families f
WHERE ({grade: f.children[0].grade}.grade > 3)
```

Concatenation, example 4:

- LINQ lambda expression

```
input.SelectMany(family => family.parents)
    .Where(parent => parents.familyName == "Wakefield");
```

- SQL

```
SELECT *
FROM p IN Families.parents
WHERE p.familyName = "Wakefield"
```

Nesting

The syntax is `input.SelectMany(x=>x.Q())` where `Q` is a `Select`, `SelectMany`, or `Where` operator.

A nested query applies the inner query to each element of the outer container. One important feature is that the inner query can refer to the fields of the elements in the outer container, like a self-join.

Nesting, example 1:

- LINQ lambda expression

```
input.SelectMany(family=>
    family.parents.Select(p => p.familyName));
```

- SQL

```
SELECT VALUE p.familyName
FROM Families f
JOIN p IN f.parents
```

Nesting, example 2:

- LINQ lambda expression

```
input.SelectMany(family =>
    family.children.Where(child => child.familyName == "Jeff"));
```

- SQL

```
SELECT *
FROM Families f
JOIN c IN f.children
WHERE c.familyName = "Jeff"
```

Nesting, example 3:

- LINQ lambda expression

```
input.SelectMany(family => family.children.Where(
    child => child.familyName == family.parents[0].familyName));
```

- SQL

```
SELECT *
FROM Families f
JOIN c IN f.children
WHERE c.familyName = f.parents[0].familyName
```

Indexing in Azure Cosmos DB - Overview

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is a schema-agnostic database that allows you to iterate on your application without having to deal with schema or index management. By default, Azure Cosmos DB automatically indexes every property for all items in your container without having to define any schema or configure secondary indexes.

The goal of this article is to explain how Azure Cosmos DB indexes data and how it uses indexes to improve query performance. It is recommended to go through this section before exploring how to customize indexing policies.

From items to trees

Every time an item is stored in a container, its content is projected as a JSON document, then converted into a tree representation. What that means is that every property of that item gets represented as a node in a tree. A pseudo root node is created as a parent to all the first-level properties of the item. The leaf nodes contain the actual scalar values carried by an item.

As an example, consider this item:

```
{
    "locations": [
        { "country": "Germany", "city": "Berlin" },
        { "country": "France", "city": "Paris" }
    ],
    "headquarters": { "country": "Belgium", "employees": 250 },
    "exports": [
        { "city": "Moscow" },
        { "city": "Athens" }
    ]
}
```

It would be represented by the following tree:

Note how arrays are encoded in the tree: every entry in an array gets an intermediate node labeled with the index of that entry within the array (0, 1 etc.).

From trees to property paths

The reason why Azure Cosmos DB transforms items into trees is because it allows properties to be referenced by their paths within those trees. To get the path for a property, we can traverse the tree from the root node to that property, and concatenate the labels of each traversed node.

Here are the paths for each property from the example item described above:

- /locations/0/country: "Germany"
- /locations/0/city: "Berlin"
- /locations/1/country: "France"
- /locations/1/city: "Paris"
- /headquarters/country: "Belgium"
- /headquarters/employees: 250
- /exports/0/city: "Moscow"
- /exports/1/city: "Athens"

When an item is written, Azure Cosmos DB effectively indexes each property's path and its corresponding value.

Index kinds

Azure Cosmos DB currently supports three kinds of indexes.

Range Index

Range index is based on an ordered tree-like structure. The range index kind is used for:

- Equality queries:

  ```
  SELECT * FROM container c WHERE c.property = 'value'
  ```

  ```
  SELECT * FROM c WHERE c.property IN ("value1", "value2", "value3")
  ```

  Equality match on an array element

  ```
    SELECT * FROM c WHERE ARRAY_CONTAINS(c.tags, "tag1")
  ```

- Range queries:

  ```
  SELECT * FROM container c WHERE c.property > 'value'
  ```

  (works for `>`, `<`, `>=`, `<=`, `!=`)

- Checking for the presence of a property:

  ```
  SELECT * FROM c WHERE IS_DEFINED(c.property)
  ```

- String system functions:

  ```
  SELECT * FROM c WHERE CONTAINS(c.property, "value")
  ```

```
SELECT * FROM c WHERE STRINGEQUALS(c.property, "value")
```

- `ORDER BY` queries:

```
SELECT * FROM container c ORDER BY c.property
```

- `JOIN` queries:

```
SELECT child FROM container c JOIN child IN c.properties WHERE child = 'value'
```

Range indexes can be used on scalar values (string or number).

Spatial index

Spatial indices enable efficient queries on geospatial objects such as - points, lines, polygons, and multipolygon. These queries use ST_DISTANCE, ST_WITHIN, ST_INTERSECTS keywords. The following are some examples that use spatial index kind:

- Geospatial distance queries:

```
SELECT * FROM container c WHERE ST_DISTANCE(c.property, { "type": "Point", "coordinates": [0.0, 10.0]
}) < 40
```

- Geospatial within queries:

```
SELECT * FROM container c WHERE ST_WITHIN(c.property, {"type": "Point", "coordinates": [0.0, 10.0] })
```

- Geospatial intersect queries:

```
SELECT * FROM c WHERE ST_INTERSECTS(c.property, { 'type':'Polygon', 'coordinates': [[ [31.8, -5],
[32, -5], [31.8, -5] ]]  })
```

Spatial indexes can be used on correctly formatted GeoJSON objects. Points, LineStrings, Polygons, and MultiPolygons are currently supported.

Composite indexes

Composite indices increase the efficiency when you are performing operations on multiple fields. The composite index kind is used for:

- `ORDER BY` queries on multiple properties:

```
SELECT * FROM container c ORDER BY c.property1, c.property2
```

- Queries with a filter and `ORDER BY`. These queries can utilize a composite index if the filter property is added to the `ORDER BY` clause.

```
SELECT * FROM container c WHERE c.property1 = 'value' ORDER BY c.property1, c.property2
```

- Queries with a filter on two or more properties where at least one property is an equality filter

```
SELECT * FROM container c WHERE c.property1 = 'value' AND c.property2 > 'value'
```

As long as one filter predicate uses one of the index kind, the query engine will evaluate that first before scanning the rest. For example, if you have a SQL query such as `SELECT * FROM c WHERE c.firstName = "Andrew" and CONTAINS(c.lastName, "Liu")`

- The above query will first filter for entries where firstName = "Andrew" by using the index. It then pass all of the firstName = "Andrew" entries through a subsequent pipeline to evaluate the CONTAINS filter predicate.
- You can speed up queries and avoid full container scans when using functions that don't use the index (e.g. CONTAINS) by adding additional filter predicates that do use the index. The order of filter clauses isn't important. The query engine is will figure out which predicates are more selective and run the query accordingly.

Querying with indexes

The paths extracted when indexing data make it easy to lookup the index when processing a query. By matching the `WHERE` clause of a query with the list of indexed paths, it is possible to identify the items that match the query predicate very quickly.

For example, consider the following query: `SELECT location FROM location IN company.locations WHERE location.country = 'France'`. The query predicate (filtering on items, where any location has "France" as its country/region) would match the path highlighted in red below:

> **NOTE**
> An `ORDER BY` clause that orders by a single property *always* needs a range index and will fail if the path it references doesn't have one. Similarly, an `ORDER BY` query which orders by multiple properties *always* needs a composite index.

Time to Live (TTL) in Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

With **Time to Live** or TTL, Azure Cosmos DB provides the ability to delete items automatically from a container after a certain time period. By default, you can set time to live at the container level and override the value on a per-item basis. After you set the TTL at a container or at an item level, Azure Cosmos DB will automatically remove these items after the time period, since the time they were last modified. Time to live value is configured in seconds. When you configure TTL, the system will automatically delete the expired items based on the TTL value, without needing a delete operation that is explicitly issued by the client application. The maximum value for TTL is 2147483647.

Deletion of expired items is a background task that consumes left-over Request Units, that is Request Units that haven't been consumed by user requests. Even after the TTL has expired, if the container is overloaded with requests and if there aren't enough RU's available, the data deletion is delayed. Data is deleted once there are enough RUs available to perform the delete operation. Though the data deletion is delayed, data is not returned by any queries (by any API) after the TTL has expired.

> This content is related to Azure Cosmos DB transactional store TTL. If you are looking for analytical store TTL, that enables NoETL HTAP scenarios through Azure Synapse Link, please click here.

Time to live for containers and items

The time to live value is set in seconds, and it is interpreted as a delta from the time that an item was last modified. You can set time to live on a container or an item within the container:

1. **Time to Live on a container** (set using `DefaultTimeToLive`):
   - If missing (or set to null), items are not expired automatically.
   - If present and the value is set to "-1", it is equal to infinity, and items don't expire by default.
   - If present and the value is set to some *non-zero* number *"n"* – items will expire *"n"* seconds after their last modified time.
2. **Time to Live on an item** (set using `ttl`):
   - This Property is applicable only if `DefaultTimeToLive` is present and it is not set to null for the parent container.
   - If present, it overrides the `DefaultTimeToLive` value of the parent container.

Time to Live configurations

- If TTL is set to *"n"* on a container, then the items in that container will expire after *n* seconds. If there are items in the same container that have their own time to live, set to -1 (indicating they do not expire) or if some items have overridden the time to live setting with a different number, these items expire based on their own configured TTL value.
- If TTL is not set on a container, then the time to live on an item in this container has no effect.
- If TTL on a container is set to -1, an item in this container that has the time to live set to n, will expire after

n seconds, and remaining items will not expire.

Examples

This section shows some examples with different time to live values assigned to container and items:

Example 1

TTL on container is set to null (DefaultTimeToLive = null)

TTL ON ITEM	RESULT
ttl = null	TTL is disabled. The item will never expire (default).
ttl = -1	TTL is disabled. The item will never expire.
ttl = 2000	TTL is disabled. The item will never expire.

Example 2

TTL on container is set to -1 (DefaultTimeToLive = -1)

TTL ON ITEM	RESULT
ttl = null	TTL is enabled. The item will never expire (default).
ttl = -1	TTL is enabled. The item will never expire.
ttl = 2000	TTL is enabled. The item will expire after 2000 seconds.

Example 3

TTL on container is set to 1000 (DefaultTimeToLive = 1000)

TTL ON ITEM	RESULT
ttl = null	TTL is enabled. The item will expire after 1000 seconds (default).
ttl = -1	TTL is enabled. The item will never expire.
ttl = 2000	TTL is enabled. The item will expire after 2000 seconds.

Unique key constraints in Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

Unique keys add a layer of data integrity to an Azure Cosmos container. You create a unique key policy when you create an Azure Cosmos container. With unique keys, you make sure that one or more values within a logical partition is unique. You also can guarantee uniqueness per partition key.

After you create a container with a unique key policy, the creation of a new or an update of an existing item resulting in a duplicate within a logical partition is prevented, as specified by the unique key constraint. The partition key combined with the unique key guarantees the uniqueness of an item within the scope of the container.

For example, consider an Azure Cosmos container with email address as the unique key constraint and `CompanyID` as the partition key. When you configure the user's email address with a unique key, each item has a unique email address within a given `CompanyID`. Two items can't be created with duplicate email addresses and with the same partition key value. In Azure Cosmos DB's SQL (Core) API, items are stored as JSON values. These JSON values are case sensitive. When you choose a property as a unique key, you can insert case sensitive values for that property. For example, If you have a unique key defined on the name property, "Gaby" is different from "gaby" and you can insert both into the container.

To create items with the same email address, but not the same first name, last name, and email address, add more paths to the unique key policy. Instead of creating a unique key based on the email address only, you also can create a unique key with a combination of the first name, last name, and email address. This key is known as a composite unique key. In this case, each unique combination of the three values within a given `CompanyID` is allowed.

For example, the container can contain items with the following values, where each item honors the unique key constraint.

COMPANYID	FIRST NAME	LAST NAME	EMAIL ADDRESS
Contoso	Gaby	Duperre	gaby@contoso.com
Contoso	Gaby	Duperre	gaby@fabrikam.com
Fabrikam	Gaby	Duperre	gaby@fabrikam.com
Fabrikam	Ivan	Duperre	gaby@fabrikam.com
Fabrkam		Duperre	gaby@fabraikam.com
Fabrkam			gaby@fabraikam.com

If you attempt to insert another item with the combinations listed in the previous table, you receive an error. The error indicates that the unique key constraint wasn't met. You receive either `Resource with specified ID or name already exists` or `Resource with specified ID, name, or unique index already exists` as a return message.

Define a unique key

You can define unique keys only when you create an Azure Cosmos container. A unique key is scoped to a logical partition. In the previous example, if you partition the container based on the ZIP code, you end up with duplicated items in each logical partition. Consider the following properties when you create unique keys:

- You can't update an existing container to use a different unique key. In other words, after a container is created with a unique key policy, the policy can't be changed.
- To set a unique key for an existing container, create a new container with the unique key constraint. Use the appropriate data migration tool to move the data from the existing container to the new container. For SQL containers, use the Data Migration tool to move data. For MongoDB containers, use mongoimport.exe or mongorestore.exe to move data.
- A unique key policy can have a maximum of 16 path values. For example, the values can be `/firstName`, `/lastName`, and `/address/zipCode`. Each unique key policy can have a maximum of 10 unique key constraints or combinations. The combined paths for each unique index constraint must not exceed 60 bytes. In the previous example, first name, last name, and email address together are one constraint. This constraint uses 3 out of the 16 possible paths.
- When a container has a unique key policy, Request Unit (RU) charges to create, update, and delete an item are slightly higher.
- Sparse unique keys are not supported. If some unique path values are missing, they're treated as null values, which take part in the uniqueness constraint. For this reason, there can be only a single item with a null value to satisfy this constraint.
- Unique key names are case-sensitive. For example, consider a container with the unique key constraint set to `/address/zipcode`. If your data has a field named `ZipCode`, Azure Cosmos DB inserts "null" as the unique key because `zipcode` isn't the same as `ZipCode`. Because of this case sensitivity, all other records with ZipCode can't be inserted because the duplicate "null" violates the unique key constraint.

Transactions and optimistic concurrency control

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

Database transactions provide a safe and predictable programming model to deal with concurrent changes to the data. Traditional relational databases, like SQL Server, allow you to write the business logic using stored-procedures and/or triggers, send it to the server for execution directly within the database engine. With traditional relational databases, you are required to deal with two different programming languages the (non-transactional) application programming language such as JavaScript, Python, C#, Java, etc. and the transactional programming language (such as T-SQL) that is natively executed by the database.

The database engine in Azure Cosmos DB supports full ACID (Atomicity, Consistency, Isolation, Durability) compliant transactions with snapshot isolation. All the database operations within the scope of a container's logical partition are transactionally executed within the database engine that is hosted by the replica of the partition. These operations include both write (updating one or more items within the logical partition) and read operations. The following table illustrates different operations and transaction types:

OPERATION	OPERATION TYPE	SINGLE OR MULTI ITEM TRANSACTION
Insert (without a pre/post trigger)	Write	Single item transaction
Insert (with a pre/post trigger)	Write and Read	Multi-item transaction
Replace (without a pre/post trigger)	Write	Single item transaction
Replace (with a pre/post trigger)	Write and Read	Multi-item transaction
Upsert (without a pre/post trigger)	Write	Single item transaction
Upsert (with a pre/post trigger)	Write and Read	Multi-item transaction
Delete (without a pre/post trigger)	Write	Single item transaction
Delete (with a pre/post trigger)	Write and Read	Multi-item transaction
Execute stored procedure	Write and Read	Multi-item transaction
System initiated execution of a merge procedure	Write	Multi-item transaction
System initiated execution of deleting items based on expiration (TTL) of an item	Write	Multi-item transaction
Read	Read	Single-item transaction
Change Feed	Read	Multi-item transaction
Paginated Read	Read	Multi-item transaction

OPERATION	OPERATION TYPE	SINGLE OR MULTI ITEM TRANSACTION
Paginated Query	Read	Multi-item transaction
Execute UDF as part of the paginated query	Read	Multi-item transaction

Multi-item transactions

Azure Cosmos DB allows you to write stored procedures, pre/post triggers, user-defined-functions (UDFs) and merge procedures in JavaScript. Azure Cosmos DB natively supports JavaScript execution inside its database engine. You can register stored procedures, pre/post triggers, user-defined-functions (UDFs) and merge procedures on a container and later execute them transactionally within the Azure Cosmos database engine. Writing application logic in JavaScript allows natural expression of control flow, variable scoping, assignment, and integration of exception handling primitives within the database transactions directly in the JavaScript language.

The JavaScript-based stored procedures, triggers, UDFs, and merge procedures are wrapped within an ambient ACID transaction with snapshot isolation across all items within the logical partition. During the course of its execution, if the JavaScript program throws an exception, the entire transaction is aborted and rolled-back. The resulting programming model is simple yet powerful. JavaScript developers get a durable programming model while still using their familiar language constructs and library primitives.

The ability to execute JavaScript directly within the database engine provides performance and transactional execution of database operations against the items of a container. Furthermore, since Azure Cosmos database engine natively supports JSON and JavaScript, there is no impedance mismatch between the type systems of an application and the database.

Optimistic concurrency control

Optimistic concurrency control allows you to prevent lost updates and deletes. Concurrent, conflicting operations are subjected to the regular pessimistic locking of the database engine hosted by the logical partition that owns the item. When two concurrent operations attempt to update the latest version of an item within a logical partition, one of them will win and the other will fail. However, if one or two operations attempting to concurrently update the same item had previously read an older value of the item, the database doesn't know if the previously read value by either or both the conflicting operations was indeed the latest value of the item. Fortunately, this situation can be detected with the **Optimistic Concurrency Control (OCC)** before letting the two operations enter the transaction boundary inside the database engine. OCC protects your data from accidentally overwriting changes that were made by others. It also prevents others from accidentally overwriting your own changes.

The concurrent updates of an item are subjected to the OCC by Azure Cosmos DB's communication protocol layer. Azure Cosmos database ensures that the client-side version of the item that you are updating (or deleting) is the same as the version of the item in the Azure Cosmos container. This ensures that your writes are protected from being overwritten accidentally by the writes of others and vice versa. In a multi-user environment, the optimistic concurrency control protects you from accidentally deleting or updating wrong version of an item. As such, items are protected against the infamous "lost update" or "lost delete" problems.

Every item stored in an Azure Cosmos container has a system defined `_etag` property. The value of the `_etag` is automatically generated and updated by the server every time the item is updated. `_etag` can be used with the client supplied `if-match` request header to allow the server to decide whether an item can be conditionally updated. The value of the `if-match` header matches the value of the `_etag` at the server, the item is then updated. If the value of the `if-match` request header is no longer current, the server rejects the operation with an "HTTP 412 Precondition failure" response message. The client then can re-fetch the item to acquire the current version of the item on the server or override the version of item in the server with its own `_etag` value for the item. In

addition, `_etag` can be used with the `if-none-match` header to determine whether a refetch of a resource is needed.

The item's `_etag` value changes every time the item is updated. For replace item operations, `if-match` must be explicitly expressed as a part of the request options. For an example, see the sample code in GitHub. `_etag` values are implicitly checked for all written items touched by the stored procedure. If any conflict is detected, the stored procedure will roll back the transaction and throw an exception. With this method, either all or no writes within the stored procedure are applied atomically. This is a signal to the application to reapply updates and retry the original client request.

Azure Cosmos DB Attachments

11/2/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB attachments are special items that contain references to an associated metadata with an external blob or media file.

Azure Cosmos DB supports two types of attachments:

- **Unmanaged Attachments** are a wrapper around an URI reference to a blob that is stored in an external service (for example, Azure Storage, OneDrive, etc.). This approach is similar to storing a URI property in a standard Azure Cosmos DB item.
- **Managed Attachments** are blobs managed and stored internally by Azure Cosmos DB and exposed via a system-generated mediaLink.

> **NOTE**
>
> Attachment is a legacy feature. Their support is scoped to offer continued functionality if you are already using this feature.
>
> Instead of using attachments, we recommend you to use Azure Blob Storage as a purpose-built blob storage service to store blob data . You can continue to store metadata related to blobs, along with reference URI links, in Azure Cosmos DB as item properties. Storing this data in Azure Cosmos DB provides the ability to query metadata and links to blobs stored in Azure Blob Storage.
>
> Microsoft is committed to provide a minimum 36-month notice prior to fully deprecating attachments – which will be announced at a further date.

Known limitations

Azure Cosmos DB's managed attachments are distinct from its support for standard items – for which it offers unlimited scalability, global distribution, and integration with other Azure services.

- Attachments aren't supported in all versions of the Azure Cosmos DB's SDKs.
- Managed attachments are limited to 2 GB of storage per database account.
- Managed attachments aren't compatible with Azure Cosmos DB's global distribution, and they aren't replicated across regions.

Migrating Attachments to Azure Blob Storage

We recommend migrating Azure Cosmos DB attachments to Azure Blob Storage by following these steps:

1. Copy attachments data from your source Azure Cosmos DB container to your target Azure Blob Storage container.
2. Validate the uploaded blob data in the target Azure Blob Storage container.
3. If applicable, add URI references to the blobs contained in Azure Blob Storage as string properties within your Azure Cosmos DB dataset.
4. Refactor your application code to read and write blobs from the new Azure Blob Storage container.

The following dotnet code sample shows how to copy attachments from Azure Cosmos DB to Azure Blob storage as part of a migration flow by using Azure Cosmos DB's .NET SDK v2 and Azure Blob Storage .NET SDK v12. Make

sure to replace the `<placeholder values>` for the source Azure Cosmos DB account and target Azure Blob storage container.

```
using System;
using System.IO;
using System.Threading.Tasks;
using Microsoft.Azure.Documents;
using Microsoft.Azure.Documents.Client;
using Azure.Storage.Blobs;
using Azure.Storage.Blobs.Models;

namespace attachments
{
    class Program
    {
        private static string cosmosAccount = "<Your_Azure_Cosmos_account_URI>";
        private static string cosmosKey = "<Your_Azure_Cosmos_account_PRIMARY_KEY>";
        private static string cosmosDatabaseName = "<Your_Azure_Cosmos_database>";
        private static string cosmosCollectionName = "<Your_Azure_Cosmos_collection>";
        private static string storageConnectionString = "<Your_Azure_Storage_connection_string>";
        private static string storageContainerName = "<Your_Azure_Storage_container_name>";
        private static DocumentClient cosmosClient = new DocumentClient(new Uri(cosmosAccount), cosmosKey);
        private static BlobServiceClient storageClient = new BlobServiceClient(storageConnectionString);
        private static BlobContainerClient storageContainerClient =
storageClient.GetBlobContainerClient(storageContainerName);

        static void Main(string[] args)
        {
            CopyAttachmentsToBlobsAsync().Wait();
        }

        private async static Task CopyAttachmentsToBlobsAsync()
        {
            Console.WriteLine("Copying Azure Cosmos DB Attachments to Azure Blob Storage ...");

            int totalCount = 0;
            string docContinuation = null;

            // Iterate through each item (document in v2) in the Azure Cosmos DB container (collection in v2)
to look for attachments.
            do
            {
                FeedResponse<dynamic> response = await cosmosClient.ReadDocumentFeedAsync(
                    UriFactory.CreateDocumentCollectionUri(cosmosDatabaseName, cosmosCollectionName),
                    new FeedOptions
                    {
                        MaxItemCount = -1,
                        RequestContinuation = docContinuation
                    });
                docContinuation = response.ResponseContinuation;

                foreach (Document document in response)
                {
                    string attachmentContinuation = null;
                    PartitionKey docPartitionKey = new PartitionKey(document.Id);

                    // Iterate through each attachment within the item (if any).
                    do
                    {
                        FeedResponse<Attachment> attachments = await cosmosClient.ReadAttachmentFeedAsync(
                            document.SelfLink,
                            new FeedOptions
                            {
                                PartitionKey = docPartitionKey,
                                RequestContinuation = attachmentContinuation
                            }
                        );
```

```
                        };
                        attachmentContinuation = attachments.ResponseContinuation;

                        foreach (var attachment in attachments)
                        {
                            // Download the attachment in to local memory.
                            MediaResponse content = await cosmosClient.ReadMediaAsync(attachment.MediaLink);

                            byte[] buffer = new byte[content.ContentLength];
                            await content.Media.ReadAsync(buffer, 0, buffer.Length);

                            // Upload the locally buffered attachment to blob storage
                            string blobId = String.Concat(document.Id, "-", attachment.Id);

                            Azure.Response<BlobContentInfo> uploadedBob = await
storageContainerClient.GetBlobClient(blobId).UploadAsync(
                                new MemoryStream(buffer, writable: false),
                                true
                            );

                            Console.WriteLine("Copied attachment ... Item Id: {0} , Attachment Id: {1}, Blob
Id: {2}", document.Id, attachment.Id, blobId);
                            totalCount++;

                            // Clean up attachment from Azure Cosmos DB.
                            // Warning: please verify you've succesfully migrated attachments to blog storage
prior to cleaning up Azure Cosmos DB.
                            // await cosmosClient.DeleteAttachmentAsync(
                            //     attachment.SelfLink,
                            //     new RequestOptions { PartitionKey = docPartitionKey }
                            // );

                            // Console.WriteLine("Cleaned up attachment ... Document Id: {0} , Attachment Id:
{1}", document.Id, attachment.Id);
                        }

                    } while (!string.IsNullOrEmpty(attachmentContinuation));
                }
            }
            while (!string.IsNullOrEmpty(docContinuation));

            Console.WriteLine("Finished copying {0} attachments to blob storage", totalCount);
        }
    }
}
```

Change feed design patterns in Azure Cosmos DB

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

The Azure Cosmos DB change feed enables efficient processing of large datasets with a high volume of writes. Change feed also offers an alternative to querying an entire dataset to identify what has changed. This document focuses on common change feed design patterns, design tradeoffs, and change feed limitations.

Azure Cosmos DB is well-suited for IoT, gaming, retail, and operational logging applications. A common design pattern in these applications is to use changes to the data to trigger additional actions. Examples of additional actions include:

- Triggering a notification or a call to an API, when an item is inserted or updated.
- Real-time stream processing for IoT or real-time analytics processing on operational data.
- Data movement such as synchronizing with a cache, a search engine, a data warehouse, or cold storage.

The change feed in Azure Cosmos DB enables you to build efficient and scalable solutions for each of these patterns, as shown in the following image:

Event computing and notifications

The Azure Cosmos DB change feed can simplify scenarios that need to trigger a notification or send a call to an API based on a certain event. You can use the Change Feed Process Library to automatically poll your container for changes and call an external API each time there is a write or update.

You can also selectively trigger a notification or send a call to an API based on specific criteria. For example, if you are reading from the change feed using Azure Functions, you can put logic into the function to only send a notification if a specific criteria has been met. While the Azure Function code would execute during each write and update, the notification would only be sent if specific criteria had been met.

Real-time stream processing

The Azure Cosmos DB change feed can be used for real-time stream processing for IoT or real-time analytics processing on operational data. For example, you might receive and store event data from devices, sensors, infrastructure and applications, and process these events in real time, using Spark. The following image shows how you can implement a lambda architecture using the Azure Cosmos DB via change feed:

In many cases, stream processing implementations first receive a high volume of incoming data into a temporary message queue such as Azure Event Hub or Apache Kafka. The change feed is a great alternative due to Azure Cosmos DB's ability to support a sustained high rate of data ingestion with guaranteed low read and write latency. The advantages of the Azure Cosmos DB change feed over a message queue include:

Data persistence

Data written to Azure Cosmos DB will show up in the change feed and be retained until deleted. Message queues typically have a maximum retention period. For example, Azure Event Hub offers a maximum data retention of 90 days.

Querying ability

In addition to reading from a Cosmos container's change feed, you can also run SQL queries on the data stored in Azure Cosmos DB. The change feed isn't a duplication of data already in the container but rather just a different mechanism of reading the data. Therefore, if you read data from the change feed, it will always be consistent with queries of the same Azure Cosmos DB container.

High availability

Azure Cosmos DB offers up to 99.999% read and write availability. Unlike many message queues, Azure Cosmos DB data can be easily globally distributed and configured with an RTO (Recovery Time Objective) of zero.

After processing items in the change feed, you can build a materialized view and persist aggregated values back in Azure Cosmos DB. If you're using Azure Cosmos DB to build a game, you can, for example, use change feed to implement real-time leaderboards based on scores from completed games.

Data movement

You can also read from the change feed for real-time data movement.

For example, the change feed helps you perform the following tasks efficiently:

- Update a cache, search index, or data warehouse with data stored in Azure Cosmos DB.
- Perform zero down-time migrations to another Azure Cosmos account or another Azure Cosmos container with a different logical partition key.

- Implement an application-level data tiering and archival. For example, you can store "hot data" in Azure Cosmos DB and age out "cold data" to other storage systems such as Azure Blob Storage.

When you have to denormalize data across partitions and containers, you can read from your container's change feed as a source for this data replication. Real-time data replication with the change feed can only guarantee eventual consistency. You can monitor how far the Change Feed Processor lags behind in processing changes in your Cosmos container.

Event sourcing

The event sourcing pattern involves using an append-only store to record the full series of actions on that data. Azure Cosmos DB's change feed is a great choice as a central data store in event sourcing architectures where all data ingestion is modeled as writes (no updates or deletes). In this case, each write to Azure Cosmos DB is an "event" and you'll have a full record of past events in the change feed. Typical uses of the events published by the central event store are for maintaining materialized views or for integration with external systems. Because there is no time limit for retention in the change feed, you can replay all past events by reading from the beginning of your Cosmos container's change feed.

You can have multiple change feed consumers subscribe to the same container's change feed. Aside from the lease container's provisioned throughput, there is no cost to utilize the change feed. The change feed is available in every container regardless of whether it is utilized.

Azure Cosmos DB is a great central append-only persistent data store in the event sourcing pattern because of its strengths in horizontal scalability and high availability. In addition, the change Feed Processor library offers an "at least once" guarantee, ensuring that you won't miss processing any events.

Current limitations

The change feed has important limitations that you should understand. While items in a Cosmos container will always remain in the change feed, the change feed is not a full operation log. There are important areas to consider when designing an application that utilizes the change feed.

Intermediate updates

Only the most recent change for a given item is included in the change feed. When processing changes, you will read the latest available item version. If there are multiple updates to the same item in a short period of time, it is possible to miss processing intermediate updates. If you would like to track updates and be able to replay past updates to an item, we recommend modeling these updates as a series of writes instead.

Deletes

The change feed does not capture deletes. If you delete an item from your container, it is also removed from the change feed. The most common method of handling this is adding a soft marker on the items that are being deleted. You can add a property called "deleted" and set it to "true" at the time of deletion. This document update will show up in the change feed. You can set a TTL on this item so that it can be automatically deleted later.

Guaranteed order

There is guaranteed order in the change feed within a partition key value but not across partition key values. You should select a partition key that gives you a meaningful order guarantee.

For example, consider a retail application using the event sourcing design pattern. In this application, different user actions are each "events" which are modeled as writes to Azure Cosmos DB. Imagine if some example events occurred in the following sequence:

1. Customer adds Item A to their shopping cart
2. Customer adds Item B to their shopping cart
3. Customer removes Item A from their shopping cart

4. Customer checks out and shopping cart contents are shipped

A materialized view of current shopping cart contents is maintained for each customer. This application must ensure that these events are processed in the order in which they occur. If, for example, the cart checkout were to be processed before Item A's removal, it is likely that the customer would have had Item A shipped, as opposed to the desired Item B. In order to guarantee that these four events are processed in order of their occurrence, they should fall within the same partition key value. If you select **username** (each customer has a unique username) as the partition key, you can guarantee that these events show up in the change feed in the same order in which they are written to Azure Cosmos DB.

Examples

Here are some real-world change feed code examples that extend beyond the scope of the samples provided in Microsoft docs:

Reading Azure Cosmos DB change feed

12/4/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API

You can work with the Azure Cosmos DB change feed using either a push model or a pull model. With a push model, the change feed processor pushes work to a client that has business logic for processing this work. However, the complexity in checking for work and storing state for the last processed work is handled within the change feed processor.

With a pull model, the client has to pull the work from the server. The client, in this case, not only has business logic for processing work but also storing state for the last processed work, handling load balancing across multiple clients processing work in parallel, and handling errors.

When reading from the Azure Cosmos DB change feed, we usually recommend using a push model because you won't need to worry about:

- Polling the change feed for future changes.
- Storing state for the last processed change. When reading from the change feed, this is automatically stored in a lease container.
- Load balancing across multiple clients consuming changes. For example, if one client can't keep up with processing changes and another has available capacity.
- Handling errors. For example, automatically retrying failed changes that weren't correctly processed after an unhandled exception in code or a transient network issue.

The majority of scenarios that use the Azure Cosmos DB change feed will use one of the push model options. However, there are some scenarios where you might want the additional low level control of the pull model. These include:

- Reading changes from a particular partition key
- Controlling the pace at which your client receives changes for processing
- Doing a one-time read of the existing data in the change feed (for example, to do a data migration)

Reading change feed with a push model

Using a push model is the easiest way to read from the change feed. There are two ways you can read from the change feed with a push model: Azure Functions Cosmos DB triggers and the change feed processor library. Azure Functions uses the change feed processor behind the scenes, so these are both very similar ways to read the change feed. Think of Azure Functions as simply a hosting platform for the change feed processor, not an entirely different way of reading the change feed.

Azure Functions

Azure Functions is the simplest option if you are just getting started using the change feed. Due to its simplicity, it is also the recommended option for most change feed use cases. When you create an Azure Functions trigger for Azure Cosmos DB, you select the container to connect, and the Azure Function gets triggered whenever there is a change in the container. Because Azure Functions uses the change feed processor behind the scenes, it automatically parallelizes change processing across your container's partitions.

Developing with Azure Functions is an easy experience and can be faster than deploying the change feed processor on your own. Triggers can be created using the Azure Functions portal or programmatically using SDKs. Visual Studio and VS Code provide support to write Azure Functions, and you can even use the Azure Functions

CLI for cross-platform development. You can write and debug the code on your desktop, and then deploy the function with one click. See Serverless database computing using Azure Functions and Using change feed with Azure Functions articles to learn more.

Change feed processor library

The change feed processor gives you more control of the change feed and still hides most complexity. The change feed processor library follows the observer pattern, where your processing function is called by the library. The change feed processor library will automatically check for changes and, if changes are found, "push" these to the client. If you have a high throughput change feed, you can instantiate multiple clients to read the change feed. The change feed processor library will automatically divide the load among the different clients. You won't have to implement any logic for load balancing across multiple clients or any logic to maintain the lease state.

The change feed processor library guarantees an "at-least-once" delivery of all of the changes. In other words, if you use the change feed processor library, your processing function will be called successfully for every item in the change feed. If there is an unhandled exception in the business logic in your processing function, the failed changes will be retried until they are processed successfully. To prevent your change feed processor from getting "stuck" continuously retrying the same changes, add logic in your processing function to write documents, upon exception, to a dead-letter queue. Learn more about error handling.

In Azure Functions, the recommendation for handling errors is the same. You should still add logic in your delegate code to write documents, upon exception, to a dead-letter queue. However, if there is an unhandled exception in your Azure Function, the change that generated the exception won't be automatically retried. If there is an unhandled exception in the business logic, the Azure Function will move on to processing the next change. The Azure Function won't retry the same failed change.

Like Azure Functions, developing with the change feed processor library is easy. However, you are responsible for deploying one or more hosts for the change feed processor. A host is an application instance that uses the change feed processor to listen for changes. While Azure Functions has capabilities for automatic scaling, you are responsible for scaling your hosts. To learn more, see using the change feed processor. The change feed processor library is part of the Azure Cosmos DB SDK V3.

Reading change feed with a pull model

The change feed pull model allows you to consume the change feed at your own pace. Changes must be requested by the client and there is no automatic polling for changes. If you want to permanently "bookmark" the last processed change (similar to the push model's lease container), you'll need to save a continuation token.

Using the change feed pull model, you get more low level control of the change feed. When reading the change feed with the pull model, you have three options:

- Read changes for an entire container
- Read changes for a specific FeedRange
- Read changes for a specific partition key value

You can parallelize the processing of changes across multiple clients, just as you can with the change feed processor. However, the pull model does not automatically handle load-balancing across clients. When you use the pull model to parallelize processing of the change feed, you'll first obtain a list of FeedRanges. A FeedRange spans a range of partition key values. You'll need to have an orchestrator process that obtains FeedRanges and distributes them among your machines. You can then use these FeedRanges to have multiple machines read the change feed in parallel.

There is no built-in "at-least-once" delivery guarantee with the pull model. The pull model gives you low level control to decide how you would like to handle errors.

> **NOTE**
> The change feed pull model is currently in preview in the Azure Cosmos DB .NET SDK only. The preview is not yet available for other SDK versions.

Change feed in APIs for Cassandra and MongoDB

Change feed functionality is surfaced as change streams in MongoDB API and Query with predicate in Cassandra API. To learn more about the implementation details for MongoDB API, see the Change streams in the Azure Cosmos DB API for MongoDB.

Native Apache Cassandra provides change data capture (CDC), a mechanism to flag specific tables for archival as well as rejecting writes to those tables once a configurable size-on-disk for the CDC log is reached. The change feed feature in Azure Cosmos DB API for Cassandra enhances the ability to query the changes with predicate via CQL. To learn more about the implementation details, see Change feed in the Azure Cosmos DB API for Cassandra.

Change feed processor in Azure Cosmos DB

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

The change feed processor is part of the Azure Cosmos DB SDK V3. It simplifies the process of reading the change feed and distribute the event processing across multiple consumers effectively.

The main benefit of change feed processor library is its fault-tolerant behavior that assures an "at-least-once" delivery of all the events in the change feed.

Components of the change feed processor

There are four main components of implementing the change feed processor:

1. **The monitored container:** The monitored container has the data from which the change feed is generated. Any inserts and updates to the monitored container are reflected in the change feed of the container.
2. **The lease container:** The lease container acts as a state storage and coordinates processing the change feed across multiple workers. The lease container can be stored in the same account as the monitored container or in a separate account.
3. **The host:** A host is an application instance that uses the change feed processor to listen for changes. Multiple instances with the same lease configuration can run in parallel, but each instance should have a different **instance name**.
4. **The delegate:** The delegate is the code that defines what you, the developer, want to do with each batch of changes that the change feed processor reads.

To further understand how these four elements of change feed processor work together, let's look at an example in the following diagram. The monitored container stores documents and uses 'City' as the partition key. We see that the partition key values are distributed in ranges that contain items. There are two host instances and the change feed processor is assigning different ranges of partition key values to each instance to maximize compute distribution. Each range is being read in parallel and its progress is maintained separately from other ranges in the lease container.

Implementing the change feed processor

The point of entry is always the monitored container, from a `Container` instance you call `GetChangeFeedProcessorBuilder`:

```
/// <summary>
/// Start the Change Feed Processor to listen for changes and process them with the HandleChangesAsync
implementation.
/// </summary>
private static async Task<ChangeFeedProcessor> StartChangeFeedProcessorAsync(
    CosmosClient cosmosClient,
    IConfiguration configuration)
{
    string databaseName = configuration["SourceDatabaseName"];
    string sourceContainerName = configuration["SourceContainerName"];
    string leaseContainerName = configuration["LeasesContainerName"];

    Container leaseContainer = cosmosClient.GetContainer(databaseName, leaseContainerName);
    ChangeFeedProcessor changeFeedProcessor = cosmosClient.GetContainer(databaseName, sourceContainerName)
        .GetChangeFeedProcessorBuilder<ToDoItem>(processorName: "changeFeedSample", HandleChangesAsync)
            .WithInstanceName("consoleHost")
            .WithLeaseContainer(leaseContainer)
            .Build();

    Console.WriteLine("Starting Change Feed Processor...");
    await changeFeedProcessor.StartAsync();
    Console.WriteLine("Change Feed Processor started.");
    return changeFeedProcessor;
}
```

Where the first parameter is a distinct name that describes the goal of this processor and the second name is the delegate implementation that will handle changes.

An example of a delegate would be:

```
/// <summary>
/// The delegate receives batches of changes as they are generated in the change feed and can process
them.
/// </summary>
static async Task HandleChangesAsync(IReadOnlyCollection<ToDoItem> changes, CancellationToken
cancellationToken)
{
    Console.WriteLine("Started handling changes...");
    foreach (ToDoItem item in changes)
    {
        Console.WriteLine($"Detected operation for item with id {item.id}, created at
{item.creationTime}.");
        // Simulate some asynchronous operation
        await Task.Delay(10);
    }

    Console.WriteLine("Finished handling changes.");
}
```

Finally you define a name for this processor instance with `WithInstanceName` and which is the container to maintain the lease state with `WithLeaseContainer`.

Calling `Build` will give you the processor instance that you can start by calling `StartAsync`.

Processing life cycle

The normal life cycle of a host instance is:

1. Read the change feed.
2. If there are no changes, sleep for a predefined amount of time (customizable with `WithPollInterval` in the Builder) and go to #1.
3. If there are changes, send them to the **delegate**.
4. When the delegate finishes processing the changes **successfully**, update the lease store with the latest processed point in time and go to #1.

Error handling

The change feed processor is resilient to user code errors. That means that if your delegate implementation has an unhandled exception (step #4), the thread processing that particular batch of changes will be stopped, and a new thread will be created. The new thread will check which was the latest point in time the lease store has for that range of partition key values, and restart from there, effectively sending the same batch of changes to the delegate. This behavior will continue until your delegate processes the changes correctly and it's the reason the change feed processor has an "at least once" guarantee, because if the delegate code throws an exception, it will retry that batch.

To prevent your change feed processor from getting "stuck" continuously retrying the same batch of changes, you should add logic in your delegate code to write documents, upon exception, to a dead-letter queue. This design ensures that you can keep track of unprocessed changes while still being able to continue to process future changes. The dead-letter queue might be another Cosmos container. The exact data store does not matter, simply that the unprocessed changes are persisted.

In addition, you can use the change feed estimator to monitor the progress of your change feed processor instances as they read the change feed. You can use this estimation to understand if your change feed processor is "stuck" or lagging behind due to available resources like CPU, memory, and network bandwidth.

Deployment unit

A single change feed processor deployment unit consists of one or more instances with the same `processorName` and lease container configuration. You can have many deployment units where each one has a different business flow for the changes and each deployment unit consisting of one or more instances.

For example, you might have one deployment unit that triggers an external API anytime there is a change in your container. Another deployment unit might move data, in real time, each time there is a change. When a change happens in your monitored container, all your deployment units will get notified.

Dynamic scaling

As mentioned before, within a deployment unit you can have one or more instances. To take advantage of the compute distribution within the deployment unit, the only key requirements are:

1. All instances should have the same lease container configuration.
2. All instances should have the same `processorName`.
3. Each instance needs to have a different instance name (`WithInstanceName`).

If these three conditions apply, then the change feed processor will, using an equal distribution algorithm, distribute all the leases in the lease container across all running instances of that deployment unit and parallelize compute. One lease can only be owned by one instance at a given time, so the maximum number of instances equals to the number of leases.

The number of instances can grow and shrink, and the change feed processor will dynamically adjust the load by redistributing accordingly.

Moreover, the change feed processor can dynamically adjust to containers scale due to throughput or storage increases. When your container grows, the change feed processor transparently handles these scenarios by dynamically increasing the leases and distributing the new leases among existing instances.

Change feed and provisioned throughput

Change feed read operations on the monitored container will consume RUs.

Operations on the lease container consume RUs. The higher the number of instances using the same lease container, the higher the potential RU consumption will be. Remember to monitor your RU consumption on the leases container if you decide to scale and increment the number of instances.

Starting time

By default, when a change feed processor starts the first time, it will initialize the leases container, and start its processing life cycle. Any changes that happened in the monitored container before the change feed processor was initialized for the first time won't be detected.

Reading from a previous date and time

It's possible to initialize the change feed processor to read changes starting at a **specific date and time**, by passing an instance of a `DateTime` to the `WithStartTime` builder extension:

```
Container leaseContainer = client.GetContainer(databaseId, Program.leasesContainer);
Container monitoredContainer = client.GetContainer(databaseId, Program.monitoredContainer);
ChangeFeedProcessor changeFeedProcessor = monitoredContainer
    .GetChangeFeedProcessorBuilder<ToDoItem>("changeFeedTime", Program.HandleChangesAsync)
        .WithInstanceName("consoleHost")
        .WithLeaseContainer(leaseContainer)
        .WithStartTime(particularPointInTime)
        .Build();
```

The change feed processor will be initialized for that specific date and time and start reading the changes that happened after.

Reading from the beginning

In other scenarios like data migrations or analyzing the entire history of a container, we need to read the change feed from **the beginning of that container's lifetime**. To do that, we can use `WithStartTime` on the builder extension, but passing `DateTime.MinValue.ToUniversalTime()`, which would generate the UTC representation of the minimum `DateTime` value, like so:

```
Container leaseContainer = client.GetContainer(databaseId, Program.leasesContainer);
Container monitoredContainer = client.GetContainer(databaseId, Program.monitoredContainer);
ChangeFeedProcessor changeFeedProcessor = monitoredContainer
    .GetChangeFeedProcessorBuilder<ToDoItem>("changeFeedBeginning", Program.HandleChangesAsync)
        .WithInstanceName("consoleHost")
        .WithLeaseContainer(leaseContainer)
        .WithStartTime(DateTime.MinValue.ToUniversalTime())
        .Build();
```

The change feed processor will be initialized and start reading changes from the beginning of the lifetime of the container.

> **NOTE**
> These customization options only work to setup the starting point in time of the change feed processor. Once the leases container is initialized for the first time, changing them has no effect.

Where to host the change feed processor

The change feed processor can be hosted in any platform that supports long running processes or tasks:

- A continuous running Azure WebJob.
- A process in an Azure Virtual Machine.
- A background job in Azure Kubernetes Service.
- An ASP.NET hosted service.

While change feed processor can run in short lived environments, because the lease container maintains the state, the startup cycle of these environments will add delay to receiving the notifications (due to the overhead of starting the processor every time the environment is started).

Serverless event-based architectures with Azure Cosmos DB and Azure Functions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Functions provides the simplest way to connect to the change feed. You can create small reactive Azure Functions that will be automatically triggered on each new event in your Azure Cosmos container's change feed.

With the Azure Functions trigger for Cosmos DB, you can leverage the Change Feed Processor's scaling and reliable event detection functionality without the need to maintain any worker infrastructure. Just focus on your Azure Function's logic without worrying about the rest of the event-sourcing pipeline. You can even mix the Trigger with any other Azure Functions bindings.

> **NOTE**
>
> Currently, the Azure Functions trigger for Cosmos DB is supported for use with the Core (SQL) API only.

Requirements

To implement a serverless event-based flow, you need:

- **The monitored container**: The monitored container is the Azure Cosmos container being monitored, and it stores the data from which the change feed is generated. Any inserts, updates to the monitored container are reflected in the change feed of the container.
- **The lease container**: The lease container maintains state across multiple and dynamic serverless Azure Function instances and enables dynamic scaling. This lease container can be manually or automatically created by the Azure Functions trigger for Cosmos DB. To automatically create the lease container, set the *CreateLeaseCollectionIfNotExists* flag in the configuration. Partitioned lease containers are required to have a `/id` partition key definition.

Create your Azure Functions trigger for Cosmos DB

Creating your Azure Function with an Azure Functions trigger for Cosmos DB is now supported across all Azure Functions IDE and CLI integrations:

- Visual Studio Extension for Visual Studio users.
- Visual Studio Code Extension for Visual Studio Code users.
- And finally Core CLI tooling for a cross-platform IDE agnostic experience.

Run your trigger locally

You can run your Azure Function locally with the Azure Cosmos DB Emulator to create and develop your serverless event-based flows without an Azure Subscription or incurring any costs.

If you want to test live scenarios in the cloud, you can Try Cosmos DB for free without any credit card or Azure subscription required.

Change feed pull model in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

With the change feed pull model, you can consume the Azure Cosmos DB change feed at your own pace. As you can already do with the change feed processor, you can use the change feed pull model to parallelize the processing of changes across multiple change feed consumers.

> **NOTE**
> The change feed pull model is currently in preview in the Azure Cosmos DB .NET SDK only. The preview is not yet available for other SDK versions.

Comparing with change feed processor

Many scenarios can process the change feed using either the change feed processor or the pull model. The pull model's continuation tokens and the change feed processor's lease container are both "bookmarks" for the last processed item (or batch of items) in the change feed.

However, you can't convert continuation tokens to a lease container (or vice versa).

> **NOTE**
> In most cases when you need to read from the change feed, the simplest option is to use the change feed processor.

You should consider using the pull model in these scenarios:

- Read changes from a particular partition key
- Control the pace at which your client receives changes for processing
- Perform a one-time read of the existing data in the change feed (for example, to do a data migration)

Here's some key differences between the change feed processor and pull model:

FEATURE	CHANGE FEED PROCESSOR	PULL MODEL
Keeping track of current point in processing change feed	Lease (stored in an Azure Cosmos DB container)	Continuation token (stored in memory or manually persisted)
Ability to replay past changes	Yes, with push model	Yes, with pull model
Polling for future changes	Automatically checks for changes based on user-specified `WithPollInterval`	Manual
Behavior where there are no new changes	Automatically wait `WithPollInterval` and recheck	Must catch exception and manually recheck
Process changes from entire container	Yes, and automatically parallelized across multiple threads/machine consuming from the same container	Yes, and manually parallelized using FeedTokens

FEATURE	CHANGE FEED PROCESSOR	PULL MODEL
Process changes from just a single partition key	Not supported	Yes
Support level	Generally available	Preview

> **NOTE**
> Unlike when reading using the change feed processor, you must explicitly handle cases where there no are no new changes.

Consuming an entire container's changes

You can create a `FeedIterator` to process the change feed using the pull model. When you initially create a `FeedIterator`, you must specify a required `ChangeFeedStartFrom` value which consists of both the starting position for reading changes as well as the desired `FeedRange`. The `FeedRange` is a range of partition key values and specifies the items that will be read from the change feed using that specific `FeedIterator`.

You can optionally specify `ChangeFeedRequestOptions` to set a `PageSizeHint`. The `PageSizeHint` is the maximum number of items that will be returned in a single page.

The `FeedIterator` comes in two flavors. In addition to the examples below that return entity objects, you can also obtain the response with `Stream` support. Streams allow you to read data without having it first deserialized, saving on client resources.

Here's an example for obtaining a `FeedIterator` that returns entity objects, in this case a `User` object:

```
FeedIterator<User> InteratorWithPOCOS = container.GetChangeFeedIterator<User>
(ChangeFeedStartFrom.Beginning());
```

Here's an example for obtaining a `FeedIterator` that returns a `Stream`:

```
FeedIterator iteratorWithStreams = container.GetChangeFeedStreamIterator<User>
(ChangeFeedStartFrom.Beginning());
```

If you don't supply a `FeedRange` to a `FeedIterator`, you can process an entire container's change feed at your own pace. Here's an example which starts reading all changes starting at the current time:

```
FeedIterator iteratorForTheEntireContainer = container.GetChangeFeedStreamIterator<User>
(ChangeFeedStartFrom.Now());

while (iteratorForTheEntireContainer.HasMoreResults)
{
    try {
        FeedResponse<User> users = await iteratorForTheEntireContainer.ReadNextAsync();

        foreach (User user in users)
            {
                Console.WriteLine($"Detected change for user with id {user.id}");
            }
    }
    catch {
        Console.WriteLine($"No new changes");
        Thread.Sleep(5000);
    }
}
```

Because the change feed is effectively an infinite list of items encompassing all future writes and updates, the value of `HasMoreResults` is always true. When you try to read the change feed and there are no new changes available, you'll receive an exception. In the above example, the exception is handled by waiting 5 seconds before rechecking for changes.

Consuming a partition key's changes

In some cases, you may only want to process a specific partition key's changes. You can obtain a `FeedIterator` for a specific partition key and process the changes the same way that you can for an entire container.

```
FeedIterator<User> iteratorForPartitionKey = container.GetChangeFeedIterator<User>
(ChangeFeedStartFrom.Beginning(FeedRange.FromPartitionKey(new PartitionKey("PartitionKeyValue"))));

while (iteratorForThePartitionKey.HasMoreResults)
{
    try {
        FeedResponse<User> users = await iteratorForThePartitionKey.ReadNextAsync();

        foreach (User user in users)
            {
                Console.WriteLine($"Detected change for user with id {user.id}");
            }
    }
    catch {
        Console.WriteLine($"No new changes");
        Thread.Sleep(5000);
    }
}
```

Using FeedRange for parallelization

In the change feed processor, work is automatically spread across multiple consumers. In the change feed pull model, you can use the `FeedRange` to parallelize the processing of the change feed. A `FeedRange` represents a range of partition key values.

Here's an example showing how to obtain a list of ranges for your container:

```
IReadOnlyList<FeedRange> ranges = await container.GetFeedRangesAsync();
```

When you obtain of list of FeedRanges for your container, you'll get one `FeedRange` per physical partition.

Using a `FeedRange`, you can then create a `FeedIterator` to parallelize the processing of the change feed across multiple machines or threads. Unlike the previous example that showed how to obtain a `FeedIterator` for the entire container or a single partition key, you can use FeedRanges to obtain multiple FeedIterators which can process the change feed in parallel.

In the case where you want to use FeedRanges, you need to have an orchestrator process that obtains FeedRanges and distributes them to those machines. This distribution could be:

- Using `FeedRange.ToJsonString` and distributing this string value. The consumers can use this value with `FeedRange.FromJsonString`
- If the distribution is in-process, passing the `FeedRange` object reference.

Here's a sample that shows how to read from the beginning of the container's change feed using two hypothetical separate machines that are reading in parallel:

Machine 1:

```
FeedIterator<User> iteratorA = container.GetChangeFeedIterator<User>
(ChangeFeedStartFrom.Beginning(ranges[0]));
while (iteratorA.HasMoreResults)
{
    try {
        FeedResponse<User> users = await iteratorA.ReadNextAsync();

        foreach (User user in users)
            {
                Console.WriteLine($"Detected change for user with id {user.id}");
            }
    }
    catch {
        Console.WriteLine($"No new changes");
        Thread.Sleep(5000);
    }
}
```

Machine 2:

```
FeedIterator<User> iteratorB = container.GetChangeFeedIterator<User>
(ChangeFeedStartFrom.Beginning(ranges[1]));
while (iteratorB.HasMoreResults)
{
    try {
        FeedResponse<User> users = await iteratorA.ReadNextAsync();

        foreach (User user in users)
            {
                Console.WriteLine($"Detected change for user with id {user.id}");
            }
    }
    catch {
        Console.WriteLine($"No new changes");
        Thread.Sleep(5000);
    }
}
```

Saving continuation tokens

You can save the position of your `FeedIterator` by creating a continuation token. A continuation token is a string value that keeps of track of your FeedIterator's last processed changes. This allows the `FeedIterator` to resume at this point later. The following code will read through the change feed since container creation. After no more

changes are available, it will persist a continuation token so that change feed consumption can be later resumed.

```
FeedIterator<User> iterator = container.GetChangeFeedIterator<User>(ChangeFeedStartFrom.Beginning());

string continuation = null;

while (iterator.HasMoreResults)
{
   try {
        FeedResponse<User> users = await iterator.ReadNextAsync();
        continuation = users.ContinuationToken;

        foreach (User user in users)
            {
                Console.WriteLine($"Detected change for user with id {user.id}");
            }
   }
    catch {
        Console.WriteLine($"No new changes");
        Thread.Sleep(5000);
    }
}

// Some time later
FeedIterator<User> iteratorThatResumesFromLastPoint = container.GetChangeFeedIterator<User>
(ChangeFeedStartFrom.ContinuationToken(continuation));
```

As long as the Cosmos container still exists, a FeedIterator's continuation token never expires.

Stored procedures, triggers, and user-defined functions

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB provides language-integrated, transactional execution of JavaScript. When using the SQL API in Azure Cosmos DB, you can write **stored procedures**, **triggers**, and **user-defined functions (UDFs)** in the JavaScript language. You can write your logic in JavaScript that executed inside the database engine. You can create and execute triggers, stored procedures, and UDFs by using Azure portal, the JavaScript language integrated query API in Azure Cosmos DB or the Cosmos DB SQL API client SDKs.

Benefits of using server-side programming

Writing stored procedures, triggers, and user-defined functions (UDFs) in JavaScript allows you to build rich applications and they have the following advantages:

- **Procedural logic:** JavaScript as a high-level programming language that provides rich and familiar interface to express business logic. You can perform a sequence of complex operations on the data.
- **Atomic transactions:** Azure Cosmos DB database operations that are performed within a single stored procedure or a trigger are atomic. This atomic functionality lets an application combine related operations into a single batch, so that either all of the operations succeed or none of them succeed.
- **Performance:** The JSON data is intrinsically mapped to the JavaScript language type system. This mapping allows for a number of optimizations like lazy materialization of JSON documents in the buffer pool and making them available on-demand to the executing code. There are other performance benefits associated with shipping business logic to the database, which includes:
  - *Batching:* You can group operations like inserts and submit them in bulk. The network traffic latency costs and the store overhead to create separate transactions are reduced significantly.
  - *Pre-compilation:* Stored procedures, triggers, and UDFs are implicitly pre-compiled to the byte code format in order to avoid compilation cost at the time of each script invocation. Due to pre-compilation, the invocation of stored procedures is fast and has a low footprint.
  - *Sequencing:* Sometimes operations need a triggering mechanism that may perform one or additional updates to the data. In addition to Atomicity, there are also performance benefits when executing on the server side.
- **Encapsulation:** Stored procedures can be used to group logic in one place. Encapsulation adds an abstraction layer on top of the data, which enables you to evolve your applications independently from the data. This layer of abstraction is helpful when the data is schema-less and you don't have to manage adding additional logic directly into your application. The abstraction lets your keep the data secure by streamlining the access from the scripts.

> **TIP**
> Stored procedures are best suited for operations that are write-heavy and require a transaction across a partition key value. When deciding whether to use stored procedures, optimize around encapsulating the maximum amount of writes possible. Generally speaking, stored procedures are not the most efficient means for doing large numbers of read or query operations, so using stored procedures to batch large numbers of reads to return to the client will not yield the desired benefit. For best performance, these read-heavy operations should be done on the client-side, using the Cosmos SDK.

Transactions

Transaction in a typical database can be defined as a sequence of operations performed as a single logical unit of work. Each transaction provides **ACID property guarantees**. ACID is a well-known acronym that stands for: **A**tomicity, **C**onsistency, **I**solation, and **D**urability.

- Atomicity guarantees that all the operations done inside a transaction are treated as a single unit, and either all of them are committed or none of them are.
- Consistency makes sure that the data is always in a valid state across transactions.
- Isolation guarantees that no two transactions interfere with each other – many commercial systems provide multiple isolation levels that can be used based on the application needs.
- Durability ensures that any change that is committed in a database will always be present.

In Azure Cosmos DB, JavaScript runtime is hosted inside the database engine. Hence, requests made within the stored procedures and the triggers execute in the same scope as the database session. This feature enables Azure Cosmos DB to guarantee ACID properties for all operations that are part of a stored procedure or a trigger. For examples, see how to implement transactions article.

Scope of a transaction

Stored procedures are associated with an Azure Cosmos container and stored procedure execution is scoped to a logical partition key. Stored procedures must include a logical partition key value during execution that defines the logical partition for the scope of the transaction. For more information, see Azure Cosmos DB partitioning article.

Commit and rollback

Transactions are natively integrated into the Azure Cosmos DB JavaScript programming model. Within a JavaScript function, all the operations are automatically wrapped under a single transaction. If the JavaScript logic in a stored procedure completes without any exceptions, all the operations within the transaction are committed to the database. Statements like `BEGIN TRANSACTION` and `COMMIT TRANSACTION` (familiar to relational databases) are implicit in Azure Cosmos DB. If there are any exceptions from the script, the Azure Cosmos DB JavaScript runtime will roll back the entire transaction. As such, throwing an exception is effectively equivalent to a `ROLLBACK TRANSACTION` in Azure Cosmos DB.

Data consistency

Stored procedures and triggers are always executed on the primary replica of an Azure Cosmos container. This feature ensures that reads from stored procedures offer strong consistency. Queries using user-defined functions can be executed on the primary or any secondary replica. Stored procedures and triggers are intended to support transactional writes – meanwhile read-only logic is best implemented as application-side logic and queries using the Azure Cosmos DB SQL API SDKs, will help you saturate the database throughput.

> **TIP**
> The queries executed within a stored procedure or trigger may not see changes to items made by the same script transaction. This statement applies both to SQL queries, such as `getContent().getCollection.queryDocuments()`, as well as integrated language queries, such as `getContext().getCollection().filter()`.

Bounded execution

All Azure Cosmos DB operations must complete within the specified timeout duration. This constraint applies to JavaScript functions - stored procedures, triggers, and user-defined functions. If an operation does not complete within that time limit, the transaction is rolled back.

You can either ensure that your JavaScript functions finish within the time limit or implement a continuation-based model to batch/resume execution. In order to simplify development of stored procedures and triggers to handle time limits, all functions under the Azure Cosmos container (for example, create, read, update, and delete of items) return a boolean value that represents whether that operation will complete. If this value is false, it is an indication that the procedure must wrap up execution because the script is consuming more time or provisioned throughput than the configured value. Operations queued prior to the first unaccepted store operation are guaranteed to complete if the stored procedure completes in time and does not queue any more requests. Thus, operations should be queued one at a time by using JavaScript's callback convention to manage the script's control flow. Because scripts are executed in a server-side environment, they are strictly governed. Scripts that repeatedly violate execution boundaries may be marked inactive and can't be executed, and they should be recreated to honor the execution boundaries.

JavaScript functions are also subject to provisioned throughput capacity. JavaScript functions could potentially end up using a large number of request units within a short time and may be rate-limited if the provisioned throughput capacity limit is reached. It is important to note that scripts consume additional throughput in addition to the throughput spent executing database operations, although these database operations are slightly less expensive than executing the same operations from the client.

Triggers

Azure Cosmos DB supports two types of triggers:

Pre-triggers

Azure Cosmos DB provides triggers that can be invoked by performing an operation on an Azure Cosmos item. For example, you can specify a pre-trigger when you are creating an item. In this case, the pre-trigger will run before the item is created. Pre-triggers cannot have any input parameters. If necessary, the request object can be used to update the document body from original request. When triggers are registered, users can specify the operations that it can run with. If a trigger was created with `TriggerOperation.Create`, this means using the trigger in a replace operation will not be permitted. For examples, see How to write triggers article.

Post-triggers

Similar to pre-triggers, post-triggers, are also associated with an operation on an Azure Cosmos item and they don't require any input parameters. They run *after* the operation has completed and have access to the response message that is sent to the client. For examples, see How to write triggers article.

> **NOTE**
> Registered triggers don't run automatically when their corresponding operations (create / delete / replace / update) happen. They have to be explicitly called when executing these operations. To learn more, see how to run triggers article.

User-defined functions

User-defined functions (UDFs) are used to extend the SQL API query language syntax and implement custom business logic easily. They can be called only within queries. UDFs do not have access to the context object and are meant to be used as compute only JavaScript. Therefore, UDFs can be run on secondary replicas. For examples, see How to write user-defined functions article.

JavaScript language-integrated query API

In addition to issuing queries using SQL API query syntax, the server-side SDK allows you to perform queries by using a JavaScript interface without any knowledge of SQL. The JavaScript query API allows you to programmatically build queries by passing predicate functions into sequence of function calls. Queries are parsed by the JavaScript runtime and are executed efficiently within Azure Cosmos DB. To learn about JavaScript query API support, see Working with JavaScript language integrated query API article. For examples, see How to write stored procedures and triggers using Javascript Query API article.

Next steps

JavaScript query API in Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

In addition to issuing queries using the SQL API in Azure Cosmos DB, the Cosmos DB server-side SDK provides a JavaScript interface for performing optimized queries in Cosmos DB Stored Procedures and Triggers. You don't have to be aware of the SQL language to use this JavaScript interface. The JavaScript query API allows you to programmatically build queries by passing predicate functions into sequence of function calls, with a syntax familiar to ECMAScript5's array built-ins and popular JavaScript libraries like Lodash. Queries are parsed by the JavaScript runtime and efficiently executed using Azure Cosmos DB indices.

Supported JavaScript functions

FUNCTION	DESCRIPTION
`chain() ... .value([callback] [, options])`	Starts a chained call that must be terminated with value().
`filter(predicateFunction [, options] [, callback])`	Filters the input using a predicate function that returns true/false in order to filter in/out input documents into the resulting set. This function behaves similar to a WHERE clause in SQL.
`flatten([isShallow] [, options] [, callback])`	Combines and flattens arrays from each input item into a single array. This function behaves similar to SelectMany in LINQ.
`map(transformationFunction [, options] [, callback])`	Applies a projection given a transformation function that maps each input item to a JavaScript object or value. This function behaves similar to a SELECT clause in SQL.
`pluck([propertyName] [, options] [, callback])`	This function is a shortcut for a map that extracts the value of a single property from each input item.
`sortBy([predicate] [, options] [, callback])`	Produces a new set of documents by sorting the documents in the input document stream in ascending order by using the given predicate. This function behaves similar to an ORDER BY clause in SQL.
`sortByDescending([predicate] [, options] [, callback])`	Produces a new set of documents by sorting the documents in the input document stream in descending order using the given predicate. This function behaves similar to an ORDER BY x DESC clause in SQL.
`unwind(collectionSelector, [resultSelector], [options], [callback])`	Performs a self-join with inner array and adds results from both sides as tuples to the result projection. For instance, joining a person document with person.pets would produce [person, pet] tuples. This is similar to SelectMany in .NET LINK.

When included inside predicate and/or selector functions, the following JavaScript constructs get automatically optimized to run directly on Azure Cosmos DB indices:

- Simple operators: `=` `+` `-` `*` `/` `%` `|` `^` `&` `==` `!=` `===` `!===` `<` `>` `<=` `>=` `||` `&&` `<<` `>>` `>>>!` `~`

- Literals, including the object literal: {}
- var, return

The following JavaScript constructs do not get optimized for Azure Cosmos DB indices:

- Control flow (for example, if, for, while)
- Function calls

For more information, see the Cosmos DB Server Side JavaScript Documentation.

SQL to JavaScript cheat sheet

The following table presents various SQL queries and the corresponding JavaScript queries. As with SQL queries, properties (for example, item.id) are case-sensitive.

> **NOTE**
>
> `__` (double-underscore) is an alias to `getContext().getCollection()` when using the JavaScript query API.

SQL	JAVASCRIPT QUERY API	DESCRIPTION
SELECT * FROM docs	__.map(function(doc) { return doc; });	Results in all documents (paginated with continuation token) as is.

SELECT
  docs.id,
  docs.message AS msg,
  docs.actions
FROM docs
	__.map(function(doc) {
	  return {
	  id: doc.id,
	  msg: doc.message,
	  actions:doc.actions
	  };
	});
		Projects the id, message (aliased to msg), and action from all documents.

SELECT *
FROM docs
WHERE
  docs.id="X998_Y998"
	__.filter(function(doc) {
	  return doc.id ==="X998_Y998";
	});
		Queries for documents with the predicate: id = "X998_Y998".

SELECT *
FROM docs
WHERE
  ARRAY_CONTAINS(docs.Tags, 123)
	__.filter(function(x) {
	  return x.Tags && x.Tags.indexOf(123) > -1;
	});
		Queries for documents that have a Tags property and Tags is an array containing the value 123.

SELECT
  docs.id,
  docs.message AS msg
FROM docs
WHERE
  docs.id="X998_Y998"
	__.chain()
	  .filter(function(doc) {
	  return doc.id ==="X998_Y998";
	  })
	  .map(function(doc) {
	  return {
	  id: doc.id,
	  msg: doc.message
	  };
	  })
	.value();
		Queries for documents with a predicate, id = "X998_Y998", and then projects the id and message (aliased to msg).

SQL	JAVASCRIPT QUERY API	DESCRIPTION

SELECT VALUE tag
FROM docs
JOIN tag IN docs.Tags
ORDER BY docs._ts
	__.chain()
	.filter(function(doc) {
	return doc.Tags &&
	Array.isArray(doc.Tags);
	})
	.sortBy(function(doc) {
	return doc._ts;
	})
	.pluck("Tags")
	.flatten()
	.value()
		Filters for documents that have an array property, Tags, and sorts the resulting documents by the _ts timestamp system property, and then projects + flattens the Tags array.

Secure access to data in Azure Cosmos DB

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

This article provides an overview of securing access to data stored in Microsoft Azure Cosmos DB.

Azure Cosmos DB uses two types of keys to authenticate users and provide access to its data and resources.

KEY TYPE	RESOURCES
Primary keys	Used for administrative resources: database accounts, databases, users, and permissions
Resource tokens	Used for application resources: containers, documents, attachments, stored procedures, triggers, and UDFs

Primary keys

Primary keys provide access to all the administrative resources for the database account. Each account consists of two primary keys: a primary key and secondary key. The purpose of dual keys is so that you can regenerate, or roll keys, providing continuous access to your account and data. To learn more about primary keys, see the Database security article.

Key rotation

The process of rotating your primary key is simple.

1. Navigate to the Azure portal to retrieve your secondary key.
2. Replace your primary key with your secondary key in your application. Make sure that all the Cosmos DB clients across all the deployments are promptly restarted and will start using the updated key.
3. Rotate the primary key in the Azure portal.
4. Validate the new primary key works against all resource. Key rotation process can take anywhere from less than a minute to hours depending on the size of the Cosmos DB account.
5. Replace the secondary key with the new primary key.

Code sample to use a primary key

The following code sample illustrates how to use a Cosmos DB account endpoint and primary key to instantiate a DocumentClient and create a database:

```
//Read the Azure Cosmos DB endpointUrl and authorization keys from config.
//These values are available from the Azure portal on the Azure Cosmos DB account blade under "Keys".
//Keep these values in a safe and secure location. Together they provide Administrative access to your Azure
Cosmos DB account.

private static readonly string endpointUrl = ConfigurationManager.AppSettings["EndPointUrl"];
private static readonly string authorizationKey = ConfigurationManager.AppSettings["AuthorizationKey"];

CosmosClient client = new CosmosClient(endpointUrl, authorizationKey);
```

The following code sample illustrates how to use the Azure Cosmos DB account endpoint and primary key to instantiate a `CosmosClient` object:

```
HOST = config.settings["host"]
MASTER_KEY = config.settings["master_key"]

DATABASE_ID = config.settings["database_id"]
CONTAINER_ID = config.settings["container_id"]
PARTITION_KEY = PartitionKey(path="/username")

# User that you want to give access to
USERNAME, USERNAME_2 = "user", "user2"

CONTAINER_ALL_PERMISSION = "CONTAINER_ALL_PERMISSION"
PARTITION_READ_PERMISSION = "PARTITION_READ_PERMISSION"
DOCUMENT_ALL_PERMISSION = "DOCUMENT_ALL_PERMISSION"

def create_user_if_not_exists(db, username):
    try:
        user = db.create_user(body={"id": username})
    except exceptions.CosmosResourceExistsError:
        user = db.get_user_client(username)

    return user

def create_permission_if_not_exists(user, permission_definition):
    try:
        permission = user.create_permission(permission_definition)
    except exceptions.CosmosResourceExistsError:
        permission = user.get_permission(permission_definition["id"])

    return permission

def token_client_upsert(container, username, item_id):
    try:
        container.upsert_item(
            {
                "id": item_id,
                "username": username,
                "msg": "This is a message for " + username,
            }
        )
    except exceptions.CosmosHttpResponseError:
        print("Error in upserting item with id '{0}'.".format(item_id))

def token_client_read_all(container):
    try:
        items = list(container.read_all_items())
        for i in items:
            print(i)
    except exceptions.CosmosResourceNotFoundError:
```

```
    except exceptions.CosmosResourceNotFoundError:
        print("Cannot read items--container '{0}' not found.".format(container.id))
    except exceptions.CosmosHttpResponseError:
        print("Error in reading items in container '{0}'.".format(container.id))

def token_client_read_item(container, username, item_id):
    try:
        item = container.read_item(item=item_id, partition_key=username)
        print(item)
    except exceptions.CosmosResourceNotFoundError:
        print("Cannot read--item with id '{0}' not found.".format(item_id))
    except exceptions.CosmosHttpResponseError:
        print("Error in reading item with id '{0}'.".format(item_id))

def token_client_delete(container, username, item_id):
    try:
        container.delete_item(item=item_id, partition_key=username)
    except exceptions.CosmosResourceNotFoundError:
        print("Cannot delete--item with id '{0}' not found.".format(item_id))
    except exceptions.CosmosHttpResponseError:
        print("Error in deleting item with id '{0}'.".format(item_id))

def token_client_query(container, username):
    try:
        for item in container.query_items(
            query="SELECT * FROM my_container c WHERE c.username=@username",
            parameters=[{"name": "@username", "value": username}],
            partition_key=username,
        ):
            print(json.dumps(item, indent=True))
    except exceptions.CosmosHttpResponseError:
        print("Error in querying item(s)")

def run_sample():
    client = cosmos_client.CosmosClient(HOST, {"masterKey": MASTER_KEY})
```

Resource tokens

Resource tokens provide access to the application resources within a database. Resource tokens:

- Provide access to specific containers, partition keys, documents, attachments, stored procedures, triggers, and UDFs.
- Are created when a user is granted permissions to a specific resource.
- Are recreated when a permission resource is acted upon on by POST, GET, or PUT call.
- Use a hash resource token specifically constructed for the user, resource, and permission.
- Are time bound with a customizable validity period. The default valid time span is one hour. Token lifetime, however, may be explicitly specified, up to a maximum of five hours.
- Provide a safe alternative to giving out the primary key.
- Enable clients to read, write, and delete resources in the Cosmos DB account according to the permissions they've been granted.

You can use a resource token (by creating Cosmos DB users and permissions) when you want to provide access to resources in your Cosmos DB account to a client that cannot be trusted with the primary key.

Cosmos DB resource tokens provide a safe alternative that enables clients to read, write, and delete resources in your Cosmos DB account according to the permissions you've granted, and without need for either a primary or read only key.

Here is a typical design pattern whereby resource tokens may be requested, generated, and delivered to clients:

1. A mid-tier service is set up to serve a mobile application to share user photos.
2. The mid-tier service possesses the primary key of the Cosmos DB account.
3. The photo app is installed on end-user mobile devices.
4. On login, the photo app establishes the identity of the user with the mid-tier service. This mechanism of identity establishment is purely up to the application.
5. Once the identity is established, the mid-tier service requests permissions based on the identity.
6. The mid-tier service sends a resource token back to the phone app.
7. The phone app can continue to use the resource token to directly access Cosmos DB resources with the permissions defined by the resource token and for the interval allowed by the resource token.
8. When the resource token expires, subsequent requests receive a 401 unauthorized exception. At this point, the phone app re-establishes the identity and requests a new resource token.

Resource token generation and management are handled by the native Cosmos DB client libraries; however, if you use REST you must construct the request/authentication headers. For more information on creating authentication headers for REST, see Access Control on Cosmos DB Resources or the source code for our .NET SDK or Node.js SDK.

For an example of a middle tier service used to generate or broker resource tokens, see the ResourceTokenBroker app.

Users

Azure Cosmos DB users are associated with a Cosmos database. Each database can contain zero or more Cosmos DB users. The following code sample shows how to create a Cosmos DB user using the Azure Cosmos DB .NET SDK v3.

```
//Create a user.
Database database = benchmark.client.GetDatabase("SalesDatabase");

User user = await database.CreateUserAsync("User 1");
```

> **NOTE**
>
> Each Cosmos DB user has a ReadAsync() method that can be used to retrieve the list of permissions associated with the user.

Permissions

A permission resource is associated with a user and assigned at the container as well as partition key level. Each user may contain zero or more permissions. A permission resource provides access to a security token that the user needs when trying to access a specific container or data in a specific partition key. There are two available access levels that may be provided by a permission resource:

- All: The user has full permission on the resource.
- Read: The user can only read the contents of the resource but cannot perform write, update, or delete operations on the resource.

> **NOTE**
> In order to run stored procedures the user must have the All permission on the container in which the stored procedure will be run.

If you enable the diagnostic logs on data-plane requests, the following two properties corresponding to the permission are logged:

- **resourceTokenPermissionId** - This property indicates the resource token permission Id that you have specified.
- **resourceTokenPermissionMode** - This property indicates the permission mode that you have set when creating the resource token. The permission mode can have values such as "all" or "read".

Code sample to create permission

The following code sample shows how to create a permission resource, read the resource token of the permission resource, and associate the permissions with the user created above.

```
// Create a permission on a container and specific partition key value
Container container = client.GetContainer("SalesDatabase", "OrdersContainer");
user.CreatePermissionAsync(
    new PermissionProperties(
        id: "permissionUser1Orders",
        permissionMode: PermissionMode.All,
        container: benchmark.container,
        resourcePartitionKey: new PartitionKey("012345")));
```

Code sample to read permission for user

The following code snippet shows how to retrieve the permission associated with the user created above and instantiate a new CosmosClient on behalf of the user, scoped to a single partition key.

```
//Read a permission, create user client session.
PermissionProperties permissionProperties = await user.GetPermission("permissionUser1Orders")

CosmosClient client = new CosmosClient(accountEndpoint: "MyEndpoint", authKeyOrResourceToken:
permissionProperties.Token);
```

Add users and assign roles

To add Azure Cosmos DB account reader access to your user account, have a subscription owner perform the following steps in the Azure portal.

1. Open the Azure portal, and select your Azure Cosmos DB account.
2. Click the **Access control (IAM)** tab, and then click **+ Add role assignment**.

3. In the **Add role assignment** pane, in the **Role** box, select **Cosmos DB Account Reader Role**.
4. In the **Assign access to box**, select **Azure AD user, group, or application**.
5. Select the user, group, or application in your directory to which you wish to grant access. You can search the directory by display name, email address, or object identifiers. The selected user, group, or application appears in the selected members list.
6. Click **Save**.

The entity can now read Azure Cosmos DB resources.

Delete or export user data

As a database service, Azure Cosmos DB enables you to search, select, modify and delete any data located in your database or containers. It is however your responsibility to use the provided APIs and define logic required to find and erase any personal data if needed. Each multi-model API (SQL, MongoDB, Gremlin, Cassandra, Table) provides different language SDKs that contain methods to search and delete data based on custom predicates. You can also enable the time to live (TTL) feature to delete data automatically after a specified period, without incurring any additional cost.

> **NOTE**
>
> For information about viewing or deleting personal data, see Azure Data Subject Requests for the GDPR. For more information about GDPR, see the GDPR section of the Service Trust portal.

Advanced Threat Protection for Azure Cosmos DB (Preview)

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

Advanced Threat Protection for Azure Cosmos DB provides an additional layer of security intelligence that detects unusual and potentially harmful attempts to access or exploit Azure Cosmos DB accounts. This layer of protection allows you to address threats, even without being a security expert, and integrate them with central security monitoring systems.

Security alerts are triggered when anomalies in activity occur. These security alerts are integrated with Azure Security Center, and are also sent via email to subscription administrators, with details of the suspicious activity and recommendations on how to investigate and remediate the threats.

> **NOTE**
>
> - Advanced Threat Protection for Azure Cosmos DB is currently available only for the SQL API.
> - Advanced Threat Protection for Azure Cosmos DB is currently not available in Azure government and sovereign cloud regions.

For a full investigation experience of the security alerts, we recommended enabling diagnostic logging in Azure Cosmos DB, which logs operations on the database itself, including CRUD operations on all documents, containers, and databases.

Threat types

Advanced Threat Protection for Azure Cosmos DB detects anomalous activities indicating unusual and potentially harmful attempts to access or exploit databases. It can currently trigger the following alerts:

- **Access from unusual locations**: This alert is triggered when there is a change in the access pattern to an Azure Cosmos account, where someone has connected to the Azure Cosmos DB endpoint from an unusual geographical location. In some cases, the alert detects a legitimate action, meaning a new application or developer's maintenance operation. In other cases, the alert detects a malicious action from a former employee, external attacker, etc.
- **Unusual data extraction**: This alert is triggered when a client is extracting an unusual amount of data from an Azure Cosmos DB account. This can be the symptom of some data exfiltration performed to transfer all the data stored in the account to an external data store.

Configure Advanced Threat Protection

You can configure advanced threat protection in any of several ways, described in the following sections.

- Portal
- REST API
- PowerShell
- ARM template
- Azure Policy

1. Launch the Azure portal at https://portal.azure.com.

2. From the Azure Cosmos DB account, from the **Settings** menu, select **Advanced security**.

3. In the **Advanced security** configuration blade:

   - Click the **Advanced Threat Protection** option to set it to **ON**.
   - Click **Save** to save the new or updated Advanced Threat Protection policy.

Azure Cosmos DB SQL SDK connectivity modes

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

How a client connects to Azure Cosmos DB has important performance implications, especially for observed client-side latency. Azure Cosmos DB offers a simple, open RESTful programming model over HTTPS called gateway mode. Additionally, it offers an efficient TCP protocol, which is also RESTful in its communication model and uses TLS for initial authentication and encrypting traffic, called direct mode.

Available connectivity modes

The two available connectivity modes are:

- Gateway mode

  Gateway mode is supported on all SDK platforms. If your application runs within a corporate network with strict firewall restrictions, gateway mode is the best choice because it uses the standard HTTPS port and a single DNS endpoint. The performance tradeoff, however, is that gateway mode involves an additional network hop every time data is read from or written to Azure Cosmos DB. We also recommend gateway connection mode when you run applications in environments that have a limited number of socket connections.

  When you use the SDK in Azure Functions, particularly in the Consumption plan, be aware of the current limits on connections.

- Direct mode

  Direct mode supports connectivity through TCP protocol and offers better performance because there are fewer network hops. The application connects directly to the backend replicas. Direct mode is currently only supported on .NET and Java SDK platforms.

These connectivity modes essentially condition the route that data plane requests - document reads and writes - take from your client machine to partitions in the Azure Cosmos DB back-end. Direct mode is the preferred option

for best performance - it allows your client to open TCP connections directly to partitions in the Azure Cosmos DB back-end and send requests *directly* with no intermediary. By contrast, in Gateway mode, requests made by your client are routed to a so-called "Gateway" server in the Azure Cosmos DB front end, which in turn fans out your requests to the appropriate partition(s) in the Azure Cosmos DB back-end.

Service port ranges

When you use direct mode, in addition to the gateway ports, you need to ensure the port range between 10000 and 20000 is open because Azure Cosmos DB uses dynamic TCP ports. When using direct mode on private endpoints, the full range of TCP ports - from 0 to 65535 should be open. If these ports aren't open and you try to use the TCP protocol, you might receive a 503 Service Unavailable error.

The following table shows a summary of the connectivity modes available for various APIs and the service ports used for each API:

CONNECTION MODE	SUPPORTED PROTOCOL	SUPPORTED SDKS	API/SERVICE PORT
Gateway	HTTPS	All SDKs	SQL (443), MongoDB (10250, 10255, 10256), Table (443), Cassandra (10350), Graph (443) The port 10250 maps to a default Azure Cosmos DB API for MongoDB instance without geo-replication. Whereas the ports 10255 and 10256 map to the instance that has geo-replication.
Direct	TCP	.NET SDK Java SDK	When using public/service endpoints: ports in the 10000 through 20000 range When using private endpoints: ports in the 0 through 65535 range

Manage an Azure Cosmos account

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes how to manage various tasks on an Azure Cosmos account using the Azure portal, Azure PowerShell, Azure CLI, and Azure Resource Manager templates.

Create an account

Azure portal

1. From the Azure portal menu or the **Home page**, select **Create a resource**.
2. On the **New** page, search for and select **Azure Cosmos DB**.
3. On the **Azure Cosmos DB** page, select **Create**.
4. On the **Create Azure Cosmos DB Account** page, enter the basic settings for the new Azure Cosmos account.

SETTING	VALUE	DESCRIPTION
Subscription	Subscription name	Select the Azure subscription that you want to use for this Azure Cosmos account.
Resource Group	Resource group name	Select a resource group, or select **Create new**, then enter a unique name for the new resource group.
Account Name	A unique name	Enter a name to identify your Azure Cosmos account. Because *documents.azure.com* is appended to the name that you provide to create your URI, use a unique name. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-44 characters in length.
API	The type of account to create	Select **Core (SQL)** to create a document database and query by using SQL syntax. The API determines the type of account to create. Azure Cosmos DB provides five APIs: Core (SQL) and MongoDB for document data, Gremlin for graph data, Azure Table, and Cassandra. Currently, you must create a separate account for each API.

SETTING	VALUE	DESCRIPTION
Capacity mode	Provisioned throughput or Serverless	Select **Provisioned throughput** to create an account in provisioned throughput mode. Select **Serverless** to create an account in serverless mode.
Apply Free Tier Discount	Apply or Do not apply	With Azure Cosmos DB free tier, you will get the first 400 RU/s and 5 GB of storage for free in an account. Learn more about free tier.
Location	The region closest to your users	Select a geographic location to host your Azure Cosmos DB account. Use the location that is closest to your users to give them the fastest access to the data.
Account Type	Production or Non-Production	Select **Production** if the account will be used for a production workload. Select **Non-Production** if the account will be used for non-production, e.g. development, testing, QA, or staging. This is an Azure resource tag setting that tunes the Portal experience but does not affect the underlying Azure Cosmos DB account. You can change this value anytime.

NOTE

You can have up to one free tier Azure Cosmos DB account per Azure subscription and must opt-in when creating the account. If you do not see the option to apply the free tier discount, this means another account in the subscription has already been enabled with free tier.

NOTE

The following options are not available if you select **Serverless** as the **Capacity mode**:

- Apply Free Tier Discount
- Geo-redundancy
- Multi-region Writes

5. Select **Review + create**. You can skip the **Network** and **Tags** sections.

6. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

7. Select **Go to resource** to go to the Azure Cosmos DB account page.

Azure CLI

Please see Create an Azure Cosmos DB account with Azure CLI

Azure PowerShell

Please see Create an Azure Cosmos DB account with PowerShell

Azure Resource Manager template

Please see Create Azure Cosmos DB account with Azure Resource Manager templates

Add/remove regions from your database account

Azure portal

1. Sign in to Azure portal.
2. Go to your Azure Cosmos account, and open the **Replicate data globally** menu.
3. To add regions, select the hexagons on the map with the **+** label that corresponds to your desired region(s). Alternatively, to add a region, select the **+ Add region** option and choose a region from the drop-down menu.
4. To remove regions, clear one or more regions from the map by selecting the blue hexagons with check marks. Or select the "wastebasket" ( ) icon next to the region on the right side.
5. To save your changes, select **OK**.

In a single-region write mode, you cannot remove the write region. You must fail over to a different region before you can delete the current write region.

In a multi-region write mode, you can add or remove any region, if you have at least one region.

Azure CLI

Please see Add or remove regions with Azure CLI

Azure PowerShell

Please see Add or remove regions with PowerShell

Configure multiple write-regions

Azure portal

Open the **Replicate Data Globally** tab and select **Enable** to enable multi-region writes. After you enable multi-region writes, all the read regions that you currently have on the account will become read and write regions.

Azure CLI

Please see Enable multiple-write regions with Azure CLI

Azure PowerShell

Please see Enable multiple-write regions with PowerShell

Resource Manager template

An account can be migrated from single write region to multiple write regions by deploying the Resource Manager template used to create the account and setting `enableMultipleWriteLocations: true`. The following Azure Resource Manager template is a bare minimum template that will deploy an Azure Cosmos account for SQL API with two regions and multiple write locations enabled.

```
{
    "$schema": "https://schema.management.azure.com/schemas/2015-01-01/deploymentTemplate.json#",
    "contentVersion": "1.0.0.0",
    "parameters": {
        "name": {
            "type": "String"
        },
        "location": {
            "type": "String",
            "defaultValue": "[resourceGroup().location]"
        },
        "primaryRegion":{
            "type":"string",
            "metadata": {
                "description": "The primary replica region for the Cosmos DB account."
            }
        },
        "secondaryRegion":{
            "type":"string",
            "metadata": {
              "description": "The secondary replica region for the Cosmos DB account."
          }
        }
    },
    "resources": [
        {
            "type": "Microsoft.DocumentDb/databaseAccounts",
            "kind": "GlobalDocumentDB",
            "name": "[parameters('name')]",
            "apiVersion": "2019-08-01",
            "location": "[parameters('location')]",
            "tags": {},
            "properties": {
                "databaseAccountOfferType": "Standard",
                "consistencyPolicy": { "defaultConsistencyLevel": "Session" },
                "locations":
                [
                    {
                        "locationName": "[parameters('primaryRegion')]",
                        "failoverPriority": 0,
                        "isZoneRedundant": false
                    },
                    {
                        "locationName": "[parameters('secondaryRegion')]",
                        "failoverPriority": 1,
                        "isZoneRedundant": false
                    }
                ],
                "enableMultipleWriteLocations": true
            }
        }
    ]
}
```

Enable automatic failover for your Azure Cosmos account

The Automatic failover option allows Azure Cosmos DB to failover to the region with the highest failover priority with no user action should a region become unavailable. When automatic failover is enabled, region priority can be modified. Account must have two or more regions to enable automatic failover.

Azure portal

1. From your Azure Cosmos account, open the **Replicate data globally** pane.

2. At the top of the pane, select **Automatic Failover**.

3. On the **Automatic Failover** pane, make sure that **Enable Automatic Failover** is set to **ON**.

4. Select **Save**.

Azure CLI

Please see Enable automatic failover with Azure CLI

Azure PowerShell

Please see Enable automatic failover with PowerShell

Set failover priorities for your Azure Cosmos account

After a Cosmos account is configured for automatic failover, the failover priority for regions can be changed.

> **IMPORTANT**
>
> You cannot modify the write region (failover priority of zero) when the account is configured for automatic failover. To change the write region, you must disable automatic failover and do a manual failover.

Azure portal

1. From your Azure Cosmos account, open the **Replicate data globally** pane.
2. At the top of the pane, select **Automatic Failover**.

3. On the **Automatic Failover** pane, make sure that **Enable Automatic Failover** is set to **ON**.
4. To modify the failover priority, drag the read regions via the three dots on the left side of the row that appear when you hover over them.
5. Select **Save**.

Azure CLI

Please see Set failover priority with Azure CLI

Azure PowerShell

Please see Set failover priority with PowerShell

Perform manual failover on an Azure Cosmos account

> **IMPORTANT**
>
> The Azure Cosmos account must be configured for manual failover for this operation to succeed.

The process for performing a manual failover involves changing the account's write region (failover priority = 0) to another region configured for the account.

> **NOTE**
>
> Accounts with multiple write regions cannot be manually failed over. For applications using the Azure Cosmos SDK, the SDK will detect when a region becomes unavailable, then redirect automatically to the next closest region if using multi-homing API in the SDK.

Azure portal

1. Go to your Azure Cosmos account, and open the **Replicate data globally** menu.
2. At the top of the menu, select **Manual Failover**.

3. On the **Manual Failover** menu, select your new write region. Select the check box to indicate that you understand this option changes your write region.
4. To trigger the failover, select **OK**.

Azure CLI

Please see Trigger manual failover with Azure CLI

Azure PowerShell

Please see Trigger manual failover with PowerShell

Next steps

For more information and examples on how to manage the Azure Cosmos account as well as database and containers, read the following articles:

- Manage Azure Cosmos DB using Azure PowerShell
- Manage Azure Cosmos DB using Azure CLI

Manage Azure Cosmos DB Core (SQL) API resources using PowerShell

12/4/2020 • 15 minutes to read • Edit Online

APPLIES TO: SQL API

The following guide describes how to use PowerShell to script and automate management of Azure Cosmos DB Core (SQL) API resources, including the Cosmos account, database, container, and throughput. For PowerShell cmdlets for other APIs see PowerShell Samples for Cassandra, PowerShell Samples for MongoDB API, PowerShell Samples for Gremlin, PowerShell Samples for Table

> **NOTE**
> Samples in this article use Az.CosmosDB management cmdlets. See the Az.CosmosDB API reference page for the latest changes.

For cross-platform management of Azure Cosmos DB, you can use the `Az` and `Az.CosmosDB` cmdlets with cross-platform PowerShell, as well as the Azure CLI, the REST API, or the Azure portal.

> **NOTE**
> This article has been updated to use the new Azure PowerShell Az module. You can still use the AzureRM module, which will continue to receive bug fixes until at least December 2020. To learn more about the new Az module and AzureRM compatibility, see Introducing the new Azure PowerShell Az module. For Az module installation instructions, see Install Azure PowerShell.

Getting Started

Follow the instructions in How to install and configure Azure PowerShell to install and sign in to your Azure account in PowerShell.

> **IMPORTANT**
> Azure Cosmos DB resources cannot be renamed as this violates how Azure Resource Manager works with resource URIs.

Azure Cosmos accounts

The following sections demonstrate how to manage the Azure Cosmos account, including:

- Create an Azure Cosmos account
- Update an Azure Cosmos account
- List all Azure Cosmos accounts in a subscription
- Get an Azure Cosmos account
- Delete an Azure Cosmos account
- Update tags for an Azure Cosmos account
- List keys for an Azure Cosmos account
- Regenerate keys for an Azure Cosmos account

- List connection strings for an Azure Cosmos account
- Modify failover priority for an Azure Cosmos account
- Trigger a manual failover for an Azure Cosmos account
- List resource locks on an Azure Cosmos DB account

Create an Azure Cosmos account

This command creates an Azure Cosmos DB database account with multiple regions, automatic failover and bounded-staleness consistency policy.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$apiKind = "Sql"
$consistencyLevel = "BoundedStaleness"
$maxStalenessInterval = 300
$maxStalenessPrefix = 100000
$locations = @()
$locations += New-AzCosmosDBLocationObject -LocationName "East US" -FailoverPriority 0 -IsZoneRedundant 0
$locations += New-AzCosmosDBLocationObject -LocationName "West US" -FailoverPriority 1 -IsZoneRedundant 0

New-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -LocationObject $locations `
    -Name $accountName `
    -ApiKind $apiKind `
    -EnableAutomaticFailover:$true `
    -DefaultConsistencyLevel $consistencyLevel `
    -MaxStalenessIntervalInSeconds $maxStalenessInterval `
    -MaxStalenessPrefix $maxStalenessPrefix
```

- `$resourceGroupName` The Azure resource group into which to deploy the Cosmos account. It must already exist.
- `$locations` The regions for the database account, the region with `FailoverPriority 0` is the write region.
- `$accountName` The name for the Azure Cosmos account. Must be unique, lowercase, include only alphanumeric and '-' characters, and between 3 and 31 characters in length.
- `$apiKind` The type of Cosmos account to create. For more information, see APIs in Cosmos DB.
- `$consistencyPolicy`, `$maxStalenessInterval`, and `$maxStalenessPrefix` The default consistency level and settings of the Azure Cosmos account. For more information, see Consistency Levels in Azure Cosmos DB.

Azure Cosmos accounts can be configured with IP Firewall, Virtual Network service endpoints, and private endpoints. For information on how to configure the IP Firewall for Azure Cosmos DB, see Configure IP Firewall. For information on how to enable service endpoints for Azure Cosmos DB, see Configure access from virtual Networks. For information on how to enable private endpoints for Azure Cosmos DB, see Configure access from private endpoints.

List all Azure Cosmos accounts in a Resource Group

This command lists all Azure Cosmos accounts in a Resource Group.

```
$resourceGroupName = "myResourceGroup"

Get-AzCosmosDBAccount -ResourceGroupName $resourceGroupName
```

Get the properties of an Azure Cosmos account

This command allows you to get the properties of an existing Azure Cosmos account.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"

Get-AzCosmosDBAccount -ResourceGroupName $resourceGroupName -Name $accountName
```

Update an Azure Cosmos account

This command allows you to update your Azure Cosmos DB database account properties. Properties that can be updated include the following:

- Adding or removing regions
- Changing default consistency policy
- Changing IP Range Filter
- Changing Virtual Network configurations
- Enabling multi-region writes

> **NOTE**
> You cannot simultaneously add or remove regions (`locations`) and change other properties for an Azure Cosmos account. Modifying regions must be performed as a separate operation from any other change to the account.

> **NOTE**
> This command allows you to add and remove regions but does not allow you to modify failover priorities or trigger a manual failover. See Modify failover priority and Trigger manual failover.

```
# Create account with two regions
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$apiKind = "Sql"
$consistencyLevel = "Session"
$enableAutomaticFailover = $true
$locations = @()
$locations += New-AzCosmosDBLocationObject -LocationName "East US" -FailoverPriority 0 -IsZoneRedundant 0
$locations += New-AzCosmosDBLocationObject -LocationName "West US" -FailoverPriority 1 -IsZoneRedundant 0

# Create the Cosmos DB account
New-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -LocationObject $locations `
    -Name $accountName `
    -ApiKind $apiKind `
    -EnableAutomaticFailover:$enableAutomaticFailover `
    -DefaultConsistencyLevel $consistencyLevel

# Add a region to the account
$locationObject2 = @()
$locationObject2 += New-AzCosmosDBLocationObject -LocationName "East US" -FailoverPriority 0 -IsZoneRedundant
0
$locationObject2 += New-AzCosmosDBLocationObject -LocationName "West US" -FailoverPriority 1 -IsZoneRedundant
0
$locationObject2 += New-AzCosmosDBLocationObject -LocationName "South Central US" -FailoverPriority 2 -
IsZoneRedundant 0

Update-AzCosmosDBAccountRegion `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -LocationObject $locationObject2

Write-Host "Update-AzCosmosDBAccountRegion returns before the region update is complete."
Write-Host "Check account in Azure portal or using Get-AzCosmosDBAccount for region status."
Write-Host "When region was added, press any key to continue."
$HOST.UI.RawUI.ReadKey("NoEcho,IncludeKeyDown") | OUT-NULL
$HOST.UI.RawUI.Flushinputbuffer()

# Remove West US region from the account
$locationObject3 = @()
$locationObject3 += New-AzCosmosDBLocationObject -LocationName "East US" -FailoverPriority 0 -IsZoneRedundant
0
$locationObject3 += New-AzCosmosDBLocationObject -LocationName "South Central US" -FailoverPriority 1 -
IsZoneRedundant 0

Update-AzCosmosDBAccountRegion `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -LocationObject $locationObject3

Write-Host "Update-AzCosmosDBAccountRegion returns before the region update is complete."
Write-Host "Check account in Azure portal or using Get-AzCosmosDBAccount for region status."
```

Enable multiple write regions for an Azure Cosmos account

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$enableAutomaticFailover = $false
$enableMultiMaster = $true

# First disable automatic failover - cannot have both automatic
# failover and multi-region writes on an account
Update-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -EnableAutomaticFailover:$enableAutomaticFailover

# Now enable multi-region writes
Update-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -EnableMultipleWriteLocations:$enableMultiMaster
```

Delete an Azure Cosmos account

This command deletes an existing Azure Cosmos account.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"

Remove-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -PassThru:$true
```

Update Tags of an Azure Cosmos account

This command sets the Azure resource tags for an Azure Cosmos account. Tags can be set both at account creation using `New-AzCosmosDBAccount` as well as on account update using `Update-AzCosmosDBAccount`.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$tags = @{dept = "Finance"; environment = "Production";}

Update-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -Tag $tags
```

List Account Keys

When you create an Azure Cosmos account, the service generates two primary access keys that can be used for authentication when the Azure Cosmos account is accessed. Read-only keys for authenticating read-only operations are also generated. By providing two access keys, Azure Cosmos DB enables you to regenerate and rotate one key at a time with no interruption to your Azure Cosmos account. Cosmos DB accounts have two read-write keys (primary and secondary) and two read-only keys (primary and secondary).

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"

Get-AzCosmosDBAccountKey `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -Type "Keys"
```

List Connection Strings

The following command retrieves connection strings to connect apps to the Cosmos DB account.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"

Get-AzCosmosDBAccountKey `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -Type "ConnectionStrings"
```

Regenerate Account Keys

Access keys to an Azure Cosmos account should be periodically regenerated to help keep connections secure. A primary and secondary access keys are assigned to the account. This allows clients to maintain access while one key at a time is regenerated. There are four types of keys for an Azure Cosmos account (Primary, Secondary, PrimaryReadonly, and SecondaryReadonly)

```
$resourceGroupName = "myResourceGroup" # Resource Group must already exist
$accountName = "mycosmosaccount" # Must be all lower case
$keyKind = "primary" # Other key kinds: secondary, primaryReadOnly, secondaryReadOnly

New-AzCosmosDBAccountKey `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -KeyKind $keyKind
```

Enable automatic failover

The following command sets a Cosmos DB account to fail over automatically to its secondary region should the primary region become unavailable.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$enableAutomaticFailover = $true
$enableMultiMaster = $false

# First disable multi-region writes - cannot have both automatic
# failover and multi-region writes on an account
Update-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -EnableMultipleWriteLocations:$enableMultiMaster

# Now enable automatic failover
Update-AzCosmosDBAccount `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -EnableAutomaticFailover:$enableAutomaticFailover
```

Modify Failover Priority

For accounts configured with Automatic Failover, you can change the order in which Cosmos will promote secondary replicas to primary should the primary become unavailable.

For the example below, assume the current failover priority is `West US 2 = 0`, `East US 2 = 1`, `South Central US = 2`. The command will change this to `West US 2 = 0`, `South Central US = 1`, `East US 2 = 2`.

Caution

Changing the location for `failoverPriority=0` will trigger a manual failover for an Azure Cosmos account. Any other priority changes will not trigger a failover.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$locations = @("West US 2", "South Central US", "East US 2") # Regions ordered by UPDATED failover priority

Update-AzCosmosDBAccountFailoverPriority `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -FailoverPolicy $locations
```

Trigger Manual Failover

For accounts configured with Manual Failover, you can fail over and promote any secondary replica to primary by modifying to `failoverPriority=0`. This operation can be used to initiate a disaster recovery drill to test disaster recovery planning.

For the example below, assume the account has a current failover priority of `West US 2 = 0` and `East US 2 = 1` and flip the regions.

Caution

Changing `locationName` for `failoverPriority=0` will trigger a manual failover for an Azure Cosmos account. Any other priority change will not trigger a failover.

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$locations = @("East US 2", "West US 2") # Regions ordered by UPDATED failover priority

Update-AzCosmosDBAccountFailoverPriority `
    -ResourceGroupName $resourceGroupName `
    -Name $accountName `
    -FailoverPolicy $locations
```

List resource locks on an Azure Cosmos DB account

Resource locks can be placed on Azure Cosmos DB resources including databases and collections. The example below shows how to list all Azure resource locks on an Azure Cosmos DB account.

```
$resourceGroupName = "myResourceGroup"
$resourceTypeAccount = "Microsoft.DocumentDB/databaseAccounts"
$accountName = "mycosmosaccount"

Get-AzResourceLock `
    -ResourceGroupName $resourceGroupName `
    -ResourceType $resourceTypeAccount `
    -ResourceName $accountName
```

Azure Cosmos DB Database

The following sections demonstrate how to manage the Azure Cosmos DB database, including:

- Create an Azure Cosmos DB database
- Create an Azure Cosmos DB database with shared throughput
- Get the throughput of an Azure Cosmos DB database
- Migrate database throughput to autoscale
- List all Azure Cosmos DB databases in an account
- Get a single Azure Cosmos DB database
- Delete an Azure Cosmos DB database
- Create a resource lock on an Azure Cosmos DB database to prevent delete

- Remove a resource lock on an Azure Cosmos DB database

Create an Azure Cosmos DB database

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"

New-AzCosmosDBSqlDatabase `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -Name $databaseName
```

Create an Azure Cosmos DB database with shared throughput

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$databaseRUs = 400

New-AzCosmosDBSqlDatabase `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -Name $databaseName `
    -Throughput $databaseRUs
```

Get the throughput of an Azure Cosmos DB database

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"

Get-AzCosmosDBSqlDatabaseThroughput `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -Name $databaseName
```

Migrate database throughput to autoscale

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"

Invoke-AzCosmosDBSqlDatabaseThroughputMigration `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -Name $databaseName `
    -ThroughputType Autoscale
```

Get all Azure Cosmos DB databases in an account

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"

Get-AzCosmosDBSqlDatabase `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName
```

Get a single Azure Cosmos DB database

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"

Get-AzCosmosDBSqlDatabase `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -Name $databaseName
```

Delete an Azure Cosmos DB database

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"

Remove-AzCosmosDBSqlDatabase `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -Name $databaseName
```

Create a resource lock on an Azure Cosmos DB database to prevent delete

```
$resourceGroupName = "myResourceGroup"
$resourceType = "Microsoft.DocumentDB/databaseAccounts/sqlDatabases"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$resourceName = "$accountName/$databaseName"
$lockName = "myResourceLock"
$lockLevel = "CanNotDelete"

New-AzResourceLock `
    -ResourceGroupName $resourceGroupName `
    -ResourceType $resourceType `
    -ResourceName $resourceName `
    -LockName $lockName `
    -LockLevel $lockLevel
```

Remove a resource lock on an Azure Cosmos DB database

```
$resourceGroupName = "myResourceGroup"
$resourceType = "Microsoft.DocumentDB/databaseAccounts/sqlDatabases"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$resourceName = "$accountName/$databaseName"
$lockName = "myResourceLock"

Remove-AzResourceLock `
    -ResourceGroupName $resourceGroupName `
    -ResourceType $resourceType `
    -ResourceName $resourceName `
    -LockName $lockName
```

Azure Cosmos DB Container

The following sections demonstrate how to manage the Azure Cosmos DB container, including:

- Create an Azure Cosmos DB container
- Create an Azure Cosmos DB container with autoscale
- Create an Azure Cosmos DB container with a large partition key

- Get the throughput of an Azure Cosmos DB container
- Migrate container throughput to autoscale
- Create an Azure Cosmos DB container with custom indexing
- Create an Azure Cosmos DB container with indexing turned off
- Create an Azure Cosmos DB container with unique key and TTL
- Create an Azure Cosmos DB container with conflict resolution
- List all Azure Cosmos DB containers in a database
- Get a single Azure Cosmos DB container in a database
- Delete an Azure Cosmos DB container
- Create a resource lock on an Azure Cosmos DB container to prevent delete
- Remove a resource lock on an Azure Cosmos DB container

Create an Azure Cosmos DB container

```
# Create an Azure Cosmos DB container with default indexes and throughput at 400 RU
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"
$throughput = 400 #minimum = 400

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -Throughput $throughput
```

Create an Azure Cosmos DB container with autoscale

```
# Create an Azure Cosmos DB container with default indexes and autoscale throughput at 4000 RU
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"
$autoscaleMaxThroughput = 4000 #minimum = 4000

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -AutoscaleMaxThroughput $autoscaleMaxThroughput
```

Create an Azure Cosmos DB container with a large partition key size

```
# Create an Azure Cosmos DB container with a large partition key value (version = 2)
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -PartitionKeyVersion 2
```

Get the throughput of an Azure Cosmos DB container

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"

Get-AzCosmosDBSqlContainerThroughput `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName
```

Migrate container throughput to autoscale

```
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"

Invoke-AzCosmosDBSqlContainerThroughputMigration `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -ThroughputType Autoscale
```

Create an Azure Cosmos DB container with custom index policy

```
# Create a container with a custom indexing policy
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"
$indexPathIncluded = "/*"
$indexPathExcluded = "/myExcludedPath/*"

$includedPathIndex = New-AzCosmosDBSqlIncludedPathIndex -DataType String -Kind Range
$includedPath = New-AzCosmosDBSqlIncludedPath -Path $indexPathIncluded -Index $includedPathIndex

$indexingPolicy = New-AzCosmosDBSqlIndexingPolicy `
    -IncludedPath $includedPath `
    -ExcludedPath $indexPathExcluded `
    -IndexingMode Consistent `
    -Automatic $true

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -IndexingPolicy $indexingPolicy
```

Create an Azure Cosmos DB container with indexing turned off

```
# Create an Azure Cosmos DB container with no indexing
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"

$indexingPolicy = New-AzCosmosDBSqlIndexingPolicy `
    -IndexingMode None

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -IndexingPolicy $indexingPolicy
```

Create an Azure Cosmos DB container with unique key policy and TTL

```
# Create a container with a unique key policy and TTL of one day
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"
$uniqueKeyPath = "/myUniqueKeyPath"
$ttlInSeconds = 86400 # Set this to -1 (or don't use it at all) to never expire

$uniqueKey = New-AzCosmosDBSqlUniqueKey `
    -Path $uniqueKeyPath

$uniqueKeyPolicy = New-AzCosmosDBSqlUniqueKeyPolicy `
    -UniqueKey $uniqueKey

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -UniqueKeyPolicy $uniqueKeyPolicy `
    -TtlInSeconds $ttlInSeconds
```

Create an Azure Cosmos DB container with conflict resolution

To write all conflicts to the ConflictsFeed and handle separately, pass `-Type "Custom" -Path ""`.

```
# Create container with last-writer-wins conflict resolution policy
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"
$conflictResolutionPath = "/myResolutionPath"

$conflictResolutionPolicy = New-AzCosmosDBSqlConflictResolutionPolicy `
    -Type LastWriterWins `
    -Path $conflictResolutionPath

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -ConflictResolutionPolicy $conflictResolutionPolicy
```

To create a conflict resolution policy to use a stored procedure, call `New-AzCosmosDBSqlConflictResolutionPolicy` and pass parameters `-Type` and `-ConflictResolutionProcedure`.

```
# Create container with custom conflict resolution policy using a stored procedure
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$partitionKeyPath = "/myPartitionKey"
$conflictResolutionSprocName = "mysproc"

$conflictResolutionSproc = "/dbs/$databaseName/colls/$containerName/sprocs/$conflictResolutionSprocName"

$conflictResolutionPolicy = New-AzCosmosDBSqlConflictResolutionPolicy `
    -Type Custom `
    -ConflictResolutionProcedure $conflictResolutionSproc

New-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName `
    -PartitionKeyKind Hash `
    -PartitionKeyPath $partitionKeyPath `
    -ConflictResolutionPolicy $conflictResolutionPolicy
```

List all Azure Cosmos DB containers in a database

```
# List all Azure Cosmos DB containers in a database
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"

Get-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName
```

Get a single Azure Cosmos DB container in a database

```
# Get a single Azure Cosmos DB container in a database
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"

Get-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName
```

Delete an Azure Cosmos DB container

```
# Delete an Azure Cosmos DB container
$resourceGroupName = "myResourceGroup"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"

Remove-AzCosmosDBSqlContainer `
    -ResourceGroupName $resourceGroupName `
    -AccountName $accountName `
    -DatabaseName $databaseName `
    -Name $containerName
```

Create a resource lock on an Azure Cosmos DB container to prevent delete

```
$resourceGroupName = "myResourceGroup"
$resourceType = "Microsoft.DocumentDB/databaseAccounts/sqlDatabases/containers"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$resourceName = "$accountName/$databaseName/$containerName"
$lockName = "myResourceLock"
$lockLevel = "CanNotDelete"

New-AzResourceLock `
    -ResourceGroupName $resourceGroupName `
    -ResourceType $resourceType `
    -ResourceName $resourceName `
    -LockName $lockName `
    -LockLevel $lockLevel
```

Remove a resource lock on an Azure Cosmos DB container

```
$resourceGroupName = "myResourceGroup"
$resourceType = "Microsoft.DocumentDB/databaseAccounts/sqlDatabases/containers"
$accountName = "mycosmosaccount"
$databaseName = "myDatabase"
$containerName = "myContainer"
$resourceName = "$accountName/$databaseName/$containerName"
$lockName = "myResourceLock"

Remove-AzResourceLock `
    -ResourceGroupName $resourceGroupName `
    -ResourceType $resourceType `
    -ResourceName $resourceName `
    -LockName $lockName
```

Manage Azure Cosmos Core (SQL) API resources using Azure CLI

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

The following guide describes common commands to automate management of your Azure Cosmos DB accounts, databases and containers using Azure CLI. Reference pages for all Azure Cosmos DB CLI commands are available in the Azure CLI Reference. You can also find more examples in Azure CLI samples for Azure Cosmos DB, including how to create and manage Cosmos DB accounts, databases and containers for MongoDB, Gremlin, Cassandra and Table API.

Prerequisites

- Use Azure Cloud Shell using the bash environment.

  Launch Cloud Shell

- If you prefer, install Azure CLI to run CLI reference commands.
  - If you're using a local install, sign in with Azure CLI by using the az login command. To finish the authentication process, follow the steps displayed in your terminal. See Sign in with Azure CLI for additional sign-in options.
  - When you're prompted, install Azure CLI extensions on first use. For more information about extensions, see Use extensions with Azure CLI.
  - Run az version to find the version and dependent libraries that are installed. To upgrade to the latest version, run az upgrade.
- This article requires version 2.12.1 or later of the Azure CLI. If using Azure Cloud Shell, the latest version is already installed.

For Azure CLI samples for other APIs see CLI Samples for Cassandra, CLI Samples for MongoDB API, CLI Samples for Gremlin, CLI Samples for Table

> **IMPORTANT**
>
> Azure Cosmos DB resources cannot be renamed as this violates how Azure Resource Manager works with resource URIs.

Azure Cosmos Accounts

The following sections demonstrate how to manage the Azure Cosmos account, including:

- Create an Azure Cosmos account
- Add or remove regions
- Enable multi-region writes
- Set regional failover priority
- Enable automatic failover
- Trigger manual failover
- List account keys

- List read-only account keys
- List connection strings
- Regenerate account key

Create an Azure Cosmos DB account

Create an Azure Cosmos DB account with SQL API, Session consistency in West US 2 and East US 2 regions:

> **IMPORTANT**
>
> The Azure Cosmos account name must be lowercase and less than 44 characters.

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount' #needs to be lower case and less than 44 characters

az cosmosdb create \
    -n $accountName \
    -g $resourceGroupName \
    --default-consistency-level Session \
    --locations regionName='West US 2' failoverPriority=0 isZoneRedundant=False \
    --locations regionName='East US 2' failoverPriority=1 isZoneRedundant=False
```

Add or remove regions

Create an Azure Cosmos account with two regions, add a region, and remove a region.

> **NOTE**
>
> You cannot simultaneously add or remove regions `locations` and change other properties for an Azure Cosmos account. Modifying regions must be performed as a separate operation than any other change to the account resource.

> **NOTE**
>
> This command allows you to add and remove regions but does not allow you to modify failover priorities or trigger a manual failover. See Set failover priority and Trigger manual failover.

```
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'

# Create an account with 2 regions
az cosmosdb create --name $accountName --resource-group $resourceGroupName \
    --locations regionName="West US 2" failoverPriority=0 isZoneRedundant=False \
    --locations regionName="East US 2" failoverPriority=1 isZoneRedundant=False

# Add a region
az cosmosdb update --name $accountName --resource-group $resourceGroupName \
    --locations regionName="West US 2" failoverPriority=0 isZoneRedundant=False \
    --locations regionName="East US 2" failoverPriority=1 isZoneRedundant=False \
    --locations regionName="South Central US" failoverPriority=2 isZoneRedundant=False

# Remove a region
az cosmosdb update --name $accountName --resource-group $resourceGroupName \
    --locations regionName="West US 2" failoverPriority=0 isZoneRedundant=False \
    --locations regionName="East US 2" failoverPriority=1 isZoneRedundant=False
```

Enable multiple write regions

Enable multi-region writes for a Cosmos account

```
# Update an Azure Cosmos account from single write region to multiple write regions
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'

# Get the account resource id for an existing account
accountId=$(az cosmosdb show -g $resourceGroupName -n $accountName --query id -o tsv)

az cosmosdb update --ids $accountId --enable-multiple-write-locations true
```

Set failover priority

Set the failover priority for an Azure Cosmos account configured for automatic failover

```
# Assume region order is initially 'West US 2'=0 'East US 2'=1 'South Central US'=2 for account
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'

# Get the account resource id for an existing account
accountId=$(az cosmosdb show -g $resourceGroupName -n $accountName --query id -o tsv)

# Make South Central US the next region to fail over to instead of East US 2
az cosmosdb failover-priority-change --ids $accountId \
    --failover-policies 'West US 2=0' 'South Central US=1' 'East US 2=2'
```

Enable automatic failover

```
# Enable automatic failover on an existing account
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'

# Get the account resource id for an existing account
accountId=$(az cosmosdb show -g $resourceGroupName -n $accountName --query id -o tsv)

az cosmosdb update --ids $accountId --enable-automatic-failover true
```

Trigger manual failover

Caution

Changing region with priority = 0 will trigger a manual failover for an Azure Cosmos account. Any other priority change will not trigger a failover.

```
# Assume region order is initially 'West US 2=0' 'East US 2=1' 'South Central US=2' for account
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'

# Get the account resource id for an existing account
accountId=$(az cosmosdb show -g $resourceGroupName -n $accountName --query id -o tsv)

# Trigger a manual failover to promote East US 2 as new write region
az cosmosdb failover-priority-change --ids $accountId \
    --failover-policies 'East US 2=0' 'South Central US=1' 'West US 2=2'
```

List all account keys

Get all keys for a Cosmos account.

```
# List all account keys
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'

az cosmosdb keys list \
   -n $accountName \
   -g $resourceGroupName
```

List read-only account keys

Get read-only keys for a Cosmos account.

```
# List read-only account keys
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'

az cosmosdb keys list \
    -n $accountName \
    -g $resourceGroupName \
    --type read-only-keys
```

List connection strings

Get the connection strings for a Cosmos account.

```
# List connection strings
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'

az cosmosdb keys list \
    -n $accountName \
    -g $resourceGroupName \
    --type connection-strings
```

Regenerate account key

Regenerate a new key for a Cosmos account.

```
# Regenerate secondary account keys
# key-kind values: primary, primaryReadonly, secondary, secondaryReadonly
az cosmosdb keys regenerate \
    -n $accountName \
    -g $resourceGroupName \
    --key-kind secondary
```

Azure Cosmos DB database

The following sections demonstrate how to manage the Azure Cosmos DB database, including:

- Create a database
- Create a database with shared throughput
- Migrate a database to autoscale throughput
- Change database throughput
- Prevent a database from being deleted

Create a database

Create a Cosmos database.

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'

az cosmosdb sql database create \
    -a $accountName \
    -g $resourceGroupName \
    -n $databaseName
```

Create a database with shared throughput

Create a Cosmos database with shared throughput.

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
throughput=400

az cosmosdb sql database create \
    -a $accountName \
    -g $resourceGroupName \
    -n $databaseName \
    --throughput $throughput
```

Migrate a database to autoscale throughput

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'

# Migrate to autoscale throughput
az cosmosdb sql database throughput migrate \
    -a $accountName \
    -g $resourceGroupName \
    -n $databaseName \
    -t 'autoscale'

# Read the new autoscale max throughput
az cosmosdb sql database throughput show \
    -g $resourceGroupName \
    -a $accountName \
    -n $databaseName \
    --query resource.autoscaleSettings.maxThroughput \
    -o tsv
```

Change database throughput

Increase the throughput of a Cosmos database by 1000 RU/s.

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
newRU=1000

# Get minimum throughput to make sure newRU is not lower than minRU
minRU=$(az cosmosdb sql database throughput show \
    -g $resourceGroupName -a $accountName -n $databaseName \
    --query resource.minimumThroughput -o tsv)

if [ $minRU -gt $newRU ]; then
    newRU=$minRU
fi

az cosmosdb sql database throughput update \
    -a $accountName \
    -g $resourceGroupName \
    -n $databaseName \
    --throughput $newRU
```

Prevent a database from being deleted

Put an Azure resource delete lock on a database to prevent it from being deleted. This feature requires locking the Cosmos account from being changed by data plane SDKs. To learn more see, Preventing changes from SDKs. Azure resource locks can also prevent a resource from being changed by specifying a `ReadOnly` lock type. For a Cosmos database, it can be used to prevent throughput from being changed.

```
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'

lockType='CanNotDelete' # CanNotDelete or ReadOnly
databaseParent="databaseAccounts/$accountName"
databaseLockName="$databaseName-Lock"

# Create a delete lock on database
az lock create --name $databaseLockName \
    --resource-group $resourceGroupName \
    --resource-type Microsoft.DocumentDB/sqlDatabases \
    --lock-type $lockType \
    --parent $databaseParent \
    --resource $databaseName

# Delete lock on database
lockid=$(az lock show --name $databaseLockName \
        --resource-group $resourceGroupName \
        --resource-type Microsoft.DocumentDB/sqlDatabases \
        --resource $databaseName \
        --parent $databaseParent \
        --output tsv --query id)
az lock delete --ids $lockid
```

Azure Cosmos DB container

The following sections demonstrate how to manage the Azure Cosmos DB container, including:

- Create a container
- Create a container with autoscale
- Create a container with TTL enabled
- Create a container with custom index policy
- Change container throughput

- Migrate a container to autoscale throughput
- Prevent a container from being deleted

Create a container

Create a Cosmos container with default index policy, partition key and RU/s of 400.

```
# Create a SQL API container
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'
partitionKey='/myPartitionKey'
throughput=400

az cosmosdb sql container create \
    -a $accountName -g $resourceGroupName \
    -d $databaseName -n $containerName \
    -p $partitionKey --throughput $throughput
```

Create a container with autoscale

Create a Cosmos container with default index policy, partition key and autoscale RU/s of 4000.

```
# Create a SQL API container
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'
partitionKey='/myPartitionKey'
maxThroughput=4000

az cosmosdb sql container create \
    -a $accountName -g $resourceGroupName \
    -d $databaseName -n $containerName \
    -p $partitionKey --max-throughput $maxThroughput
```

Create a container with TTL

Create a Cosmos container with TTL enabled.

```
# Create an Azure Cosmos container with TTL of one day
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'

az cosmosdb sql container update \
    -g $resourceGroupName \
    -a $accountName \
    -d $databaseName \
    -n $containerName \
    --ttl=86400
```

Create a container with a custom index policy

Create a Cosmos container with a custom index policy, a spatial index, composite index, a partition key and RU/s of 400.

```
# Create a SQL API container
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'
partitionKey='/myPartitionKey'
throughput=400

# Generate a unique 10 character alphanumeric string to ensure unique resource names
uniqueId=$(env LC_CTYPE=C tr -dc 'a-z0-9' < /dev/urandom | fold -w 10 | head -n 1)

# Define the index policy for the container, include spatial and composite indexes
idxpolicy=$(cat << EOF
{
    "indexingMode": "consistent",
    "includedPaths": [
        {"path": "/*"}
    ],
    "excludedPaths": [
        { "path": "/headquarters/employees/?"}
    ],
    "spatialIndexes": [
        {"path": "/*", "types": ["Point"]}
    ],
    "compositeIndexes":[
        [
            { "path":"/name", "order":"ascending" },
            { "path":"/age", "order":"descending" }
        ]
    ]
}
EOF
)
# Persist index policy to json file
echo "$idxpolicy" > "idxpolicy-$uniqueId.json"

az cosmosdb sql container create \
    -a $accountName -g $resourceGroupName \
    -d $databaseName -n $containerName \
    -p $partitionKey --throughput $throughput \
    --idx @idxpolicy-$uniqueId.json

# Clean up temporary index policy file
rm -f "idxpolicy-$uniqueId.json"
```

Change container throughput

Increase the throughput of a Cosmos container by 1000 RU/s.

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'
newRU=1000

# Get minimum throughput to make sure newRU is not lower than minRU
minRU=$(az cosmosdb sql container throughput show \
    -g $resourceGroupName -a $accountName -d $databaseName \
    -n $containerName --query resource.minimumThroughput -o tsv)

if [ $minRU -gt $newRU ]; then
    newRU=$minRU
fi

az cosmosdb sql container throughput update \
    -a $accountName \
    -g $resourceGroupName \
    -d $databaseName \
    -n $containerName \
    --throughput $newRU
```

Migrate a container to autoscale throughput

```
resourceGroupName='MyResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'

# Migrate to autoscale throughput
az cosmosdb sql container throughput migrate \
    -a $accountName \
    -g $resourceGroupName \
    -d $databaseName \
    -n $containerName \
    -t 'autoscale'

# Read the new autoscale max throughput
az cosmosdb sql container throughput show \
    -g $resourceGroupName \
    -a $accountName \
    -d $databaseName \
    -n $containerName \
    --query resource.autoscaleSettings.maxThroughput \
    -o tsv
```

Prevent a container from being deleted

Put an Azure resource delete lock on a container to prevent it from being deleted. This feature requires locking the Cosmos account from being changed by data plane SDKs. To learn more see, Preventing changes from SDKs. Azure resource locks can also prevent a resource from being changed by specifying a `ReadOnly` lock type. For a Cosmos container, this can be used to prevent throughput or any other property from being changed.

```
resourceGroupName='myResourceGroup'
accountName='mycosmosaccount'
databaseName='database1'
containerName='container1'

lockType='CanNotDelete' # CanNotDelete or ReadOnly
databaseParent="databaseAccounts/$accountName"
containerParent="databaseAccounts/$accountName/sqlDatabases/$databaseName"
containerLockName="$containerName-Lock"

# Create a delete lock on container
az lock create --name $containerLockName \
    --resource-group $resourceGroupName \
    --resource-type Microsoft.DocumentDB/containers \
    --lock-type $lockType \
    --parent $containerParent \
    --resource $containerName

# Delete lock on container
lockid=$(az lock show --name $containerLockName \
        --resource-group $resourceGroupName \
        --resource-type Microsoft.DocumentDB/containers \
        --resource-name $containerName \
        --parent $containerParent \
        --output tsv --query id)
az lock delete --ids $lockid
```

Manage Azure Cosmos DB Core (SQL) API resources with Azure Resource Manager templates

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

In this article, you learn how to use Azure Resource Manager templates to help deploy and manage your Azure Cosmos DB accounts, databases, and containers.

This article only shows Azure Resource Manager template examples for Core (SQL) API accounts. You can also find template examples for Cassandra, Gremlin, MongoDB, and Table APIs.

IMPORTANT

- Account names are limited to 44 characters, all lowercase.
- To change the throughput values, redeploy the template with updated RU/s.
- When you add or remove locations to an Azure Cosmos account, you can't simultaneously modify other properties. These operations must be done separately.
- Azure Cosmos DB resources cannot be renamed as this violates how Azure Resource Manager works with resource URIs.

To create any of the Azure Cosmos DB resources below, copy the following example template into a new json file. You can optionally create a parameters json file to use when deploying multiple instances of the same resource with different names and values. There are many ways to deploy Azure Resource Manager templates including, Azure portal, Azure CLI, Azure PowerShell and GitHub.

Azure Cosmos account with autoscale throughput

This template creates an Azure Cosmos account in two regions with options for consistency and failover, with database and container configured for autoscale throughput that has most policy options enabled. This template is also available for one-click deploy from Azure Quickstart Templates Gallery.

Deploy to Azure

```
{
    "$schema": "https://schema.management.azure.com/schemas/2019-04-01/deploymentTemplate.json#",
    "contentVersion": "1.0.0.0",
    "parameters": {
        "accountName": {
            "type": "string",
            "defaultValue": "[concat('sql-', uniqueString(resourceGroup().id))]",
            "metadata": {
                "description": "Cosmos DB account name, max length 44 characters, lowercase"
            }
        },
        "location": {
            "type": "string",
            "defaultValue": "[resourceGroup().location]",
            "metadata": {
                "description": "Location for the Cosmos DB account."
            }
        },
        "primaryRegion":{
            "type":"string",
```

```
            "metadata": {
                "description": "The primary replica region for the Cosmos DB account."
            }
        },
        "secondaryRegion":{
            "type":"string",
            "metadata": {

Azure Cosmos DB container with server-side functionality

This template creates an Azure Cosmos account, database and container with with a stored procedure, trigger, and user-defined function. This template is also available for one-click deploy from Azure Quickstart Templates Gallery.

Deploy to Azure

```
{
    "$schema": "https://schema.management.azure.com/schemas/2019-04-01/deploymentTemplate.json#",
    "contentVersion": "1.0.0.0",
    "parameters": {
        "accountName": {
            "type": "string",
            "defaultValue": "[concat('cosmos-', uniqueString(resourceGroup().id))]",
            "metadata": {
                "description": "Cosmos DB account name"
            }
```

```
        },
        "location": {
            "type": "string",
            "defaultValue": "[resourceGroup().location]",

Free tier Azure Cosmos DB account

This template creates a free-tier Azure Cosmos account and a database with shared throughput that can be shared with up to 25 containers. This template is also available for one-click deploy from Azure Quickstart Templates Gallery.

Deploy to Azure

```
{
    "$schema": "https://schema.management.azure.com/schemas/2019-04-01/deploymentTemplate.json#",
    "contentVersion": "1.0.0.0",
    "parameters": {
        "accountName": {
            "type": "string",
            "defaultValue": "[concat('cosmos-', uniqueString(resourceGroup().id))]",
            "metadata": {
                "description": "Cosmos DB account name"
            }
        },
        "location": {
            "type": "string",
            "defaultValue": "[resourceGroup().location]",
            "metadata": {

Move an Azure Cosmos DB account to another region

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes how to either:

- Move a region where data is replicated in Azure Cosmos DB.
- Migrate account (Azure Resource Manager) metadata and data from one region to another.

Move data from one region to another

Azure Cosmos DB supports data replication natively, so moving data from one region to another is simple. You can accomplish it by using the Azure portal, Azure PowerShell, or the Azure CLI. It involves the following steps:

1. Add a new region to the account.

   To add a new region to an Azure Cosmos DB account, see Add/remove regions to an Azure Cosmos DB account.

2. Perform a manual failover to the new region.

   When the region that's being removed is currently the write region for the account, you'll need to start a failover to the new region added in the previous step. This is a zero-downtime operation. If you're moving a read region in a multiple-region account, you can skip this step.

   To start a failover, see Perform manual failover on an Azure Cosmos account.

3. Remove the original region.

   To remove a region from an Azure Cosmos DB account, see Add/remove regions from your Azure Cosmos DB account.

Migrate Azure Cosmos DB account metadata

Azure Cosmos DB does not natively support migrating account metadata from one region to another. To migrate both the account metadata and customer data from one region to another, you must create a new account in the desired region and then copy the data manually.

A near-zero-downtime migration for the SQL API requires the use of the change feed or a tool that uses it. If you're migrating the MongoDB API, the Cassandra API, or another API, or to learn more about options for migrating data between accounts, see Options to migrate your on-premises or cloud data to Azure Cosmos DB.

The following steps demonstrate how to migrate an Azure Cosmos DB account for the SQL API and its data from one region to another:

1. Create a new Azure Cosmos DB account in the desired region.

   To create a new account via the Azure portal, PowerShell, or the Azure CLI, see Create an Azure Cosmos DB account.

2. Create a new database and container.

To create a new database and container, see Create an Azure Cosmos container.

3. Migrate data by using the Azure Cosmos DB Live Data Migrator tool.

   To migrate data with near zero downtime, see Azure Cosmos DB Live Data Migrator tool.

4. Update the application connection string.

   With the Live Data Migrator tool still running, update the connection information in the new deployment of your application. You can retrieve the endpoints and keys for your application from the Azure portal.

5. Redirect requests to the new application.

   After the new application is connected to Azure Cosmos DB, you can redirect client requests to your new deployment.

6. Delete any resources that you no longer need.

   With requests now fully redirected to the new instance, you can delete the old Azure Cosmos DB account and the Live Data Migrator tool.

Next steps

For more information and examples on how to manage the Azure Cosmos account as well as databases and containers, read the following articles:

- Manage an Azure Cosmos account
- Change feed in Azure Cosmos DB

Prevent Azure Cosmos DB resources from being deleted or changed

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

As an administrator, you may need to lock an Azure Cosmos account, database or container to prevent other users in your organization from accidentally deleting or modifying critical resources. You can set the lock level to CanNotDelete or ReadOnly.

- **CanNotDelete** means authorized users can still read and modify a resource, but they can't delete the resource.
- **ReadOnly** means authorized users can read a resource, but they can't delete or update the resource. Applying this lock is similar to restricting all authorized users to the permissions granted by the Reader role.

How locks are applied

When you apply a lock at a parent scope, all resources within that scope inherit the same lock. Even resources you add later inherit the lock from the parent. The most restrictive lock in the inheritance takes precedence.

Unlike Azure role-based access control, you use management locks to apply a restriction across all users and roles. To learn about Azure RBAC for Azure Cosmos DB see, Azure role-based access control in Azure Cosmos DB.

Resource Manager locks apply only to operations that happen in the management plane, which consists of operations sent to https://management.azure.com. The locks don't restrict how resources perform their own functions. Resource changes are restricted, but resource operations aren't restricted. For example, a ReadOnly lock on an Azure Cosmos container prevents you from deleting or modifying the container. It doesn't prevent you from creating, updating, or deleting data in the container. Data transactions are permitted because those operations aren't sent to https://management.azure.com.

Manage locks

> **WARNING**
>
> Resource locks do not work for changes made by users accessing Azure Cosmos DB using account keys unless the Azure Cosmos account is first locked by enabling the disableKeyBasedMetadataWriteAccess property. Care should be taken before enabling this property to ensure it does not break existing applications that make changes to resources using any SDK, Azure portal or 3rd party tools that connect via account keys and modify resources such as changing throughput, updating index policies, etc. To learn more and to go through a checklist to ensure your applications continue to function see, Preventing changes from the Azure Cosmos DB SDKs

PowerShell

```
$resourceGroupName = "myResourceGroup"
$accountName = "my-cosmos-account"
$lockName = "$accountName-Lock"

# First, update the account to prevent changes by anything that connects via account keys
Update-AzCosmosDBAccount -ResourceGroupName $resourceGroupName -Name $accountName -
DisableKeyBasedMetadataWriteAccess true

# Create a Delete Lock on an Azure Cosmos account resource and all child resources
New-AzResourceLock `
    -ApiVersion "2020-04-01" `
    -ResourceType "Microsoft.DocumentDB/databaseAccounts" `
    -ResourceGroupName $resourceGroupName `
    -ResourceName $accountName `
    -LockName $lockName `
    -LockLevel "CanNotDelete" # CanNotDelete or ReadOnly
```

Azure CLI

```
resourceGroupName='myResourceGroup'
accountName='my-cosmos-account'
$lockName="$accountName-Lock"

# First, update the account to prevent changes by anything that connects via account keys
az cosmosdb update  --name $accountName --resource-group $resourceGroupName  --disable-key-based-metadata-
write-access true

# Create a Delete Lock on an Azure Cosmos account resource
az lock create --name $lockName \
    --resource-group $resourceGroupName \
    --resource-type Microsoft.DocumentDB/databaseAccount \
    --lock-type 'CanNotDelete' # CanNotDelete or ReadOnly \
    --resource $accountName
```

Template

When applying a lock to an Azure Cosmos DB resource, use the following formats:

- name - `{resourceName}/Microsoft.Authorization/{lockName}`
- type - `{resourceProviderNamespace}/{resourceType}/providers/locks`

> **IMPORTANT**
>
> When modifying an existing Azure Cosmos account, make sure to include the other properties for your account and child resources when redploying with this property. Do not deploy this template as is or it will reset all of your account properties.

```
"resources": [
    {
        "type": "Microsoft.DocumentDB/databaseAccounts",
        "name": "[variables('accountName')]",

Configure multi-region writes in your applications that use Azure Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

Once an account has been created with multiple write regions enabled, you must make two changes in your application to the ConnectionPolicy for the DocumentClient to enable the multi-region writes and multi-homing capabilities in Azure Cosmos DB. Within the ConnectionPolicy, set UseMultipleWriteLocations to true and pass the name of the region where the application is deployed to SetCurrentLocation. This will populate the PreferredLocations property based on the geo-proximity from location passed in. If a new region is later added to the account, the application does not have to be updated or redeployed, it will automatically detect the closer region and will auto-home on to it should a regional event occur.

> **NOTE**
>
> Cosmos accounts initially configured with single write region can be configured to multiple write regions with zero down time. To learn more see, Configure multiple-write regions

Azure portal

To enable multi-region writes from Azure portal, use the following steps:

1. Sign-in to the Azure portal.
2. Navigate to your Azure Cosmos account and from the menu, open the **Replicate data globally** pane.
3. Under the **Multi-region writes** option, choose **enable**. It automatically adds the existing regions to read and write regions.
4. You can add additional regions by selecting the icons on the map or by selecting the **Add region** button. All the regions you add will have both read and writes enabled.
5. After you update the region list, select **save** to apply the changes.

.NET SDK v2

To enable multi-region writes in your application, set `UseMultipleWriteLocations` to `true`. Also, set `SetCurrentLocation` to the region in which the application is being deployed and where Azure Cosmos DB is replicated:

```
ConnectionPolicy policy = new ConnectionPolicy
    {
        ConnectionMode = ConnectionMode.Direct,
        ConnectionProtocol = Protocol.Tcp,
        UseMultipleWriteLocations = true
    };
policy.SetCurrentLocation("West US 2");
```

.NET SDK v3

To enable multi-region writes in your application, set `ApplicationRegion` to the region in which the application is being deployed and where Cosmos DB is replicated:

```
CosmosClient cosmosClient = new CosmosClient(
    "<connection-string-from-portal>",
    new CosmosClientOptions()
    {
        ApplicationRegion = Regions.WestUS2,
    });
```

Optionally, you can use the `CosmosClientBuilder` and `WithApplicationRegion` to achieve the same result:

```
CosmosClientBuilder cosmosClientBuilder = new CosmosClientBuilder("<connection-string-from-portal>")
            .WithApplicationRegion(Regions.WestUS2);
CosmosClient client = cosmosClientBuilder.Build();
```

Java V4 SDK

To enable multi-region writes in your application, call `.multipleWriteRegionsEnabled(true)` and `.preferredRegions(preferredRegions)` in the client builder, where `preferredRegions` is a `List` containing one element - that is the region in which the application is being deployed and where Cosmos DB is replicated:

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
ArrayList<String> preferredRegions = new ArrayList<String>();
preferredRegions.add(region);

CosmosAsyncClient client =
        new CosmosClientBuilder()
                .endpoint(HOST)
                .key(MASTER_KEY)
                .multipleWriteRegionsEnabled(true)
                .preferredRegions(preferredRegions)
                .buildAsyncClient();
```

Async Java V2 SDK

The Java V2 SDK used the Maven com.microsoft.azure::azure-cosmosdb. To enable multi-region writes in your application, set `policy.setUsingMultipleWriteLocations(true)` and set `policy.setPreferredLocations` to the region in which the application is being deployed and where Cosmos DB is replicated:

```
ConnectionPolicy policy = new ConnectionPolicy();
policy.setUsingMultipleWriteLocations(true);
policy.setPreferredLocations(Collections.singletonList(region));

AsyncDocumentClient client =
    new AsyncDocumentClient.Builder()
        .withMasterKeyOrResourceToken(this.accountKey)
        .withServiceEndpoint(this.accountEndpoint)
        .withConsistencyLevel(ConsistencyLevel.Eventual)
        .withConnectionPolicy(policy).build();
```

Node.js, JavaScript, and TypeScript SDKs

To enable multi-region writes in your application, set `connectionPolicy.UseMultipleWriteLocations` to `true`. Also, set `connectionPolicy.PreferredLocations` to the region in which the application is being deployed and where Cosmos DB is replicated:

```
const connectionPolicy: ConnectionPolicy = new ConnectionPolicy();
connectionPolicy.UseMultipleWriteLocations = true;
connectionPolicy.PreferredLocations = [region];

const client = new CosmosClient({
  endpoint: config.endpoint,
  auth: { masterKey: config.key },
  connectionPolicy,
  consistencyLevel: ConsistencyLevel.Eventual
});
```

Python SDK

To enable multi-region writes in your application, set `connection_policy.UseMultipleWriteLocations` to `true`. Also, set `connection_policy.PreferredLocations` to the region in which the application is being deployed and where Cosmos DB is replicated.

```
connection_policy = documents.ConnectionPolicy()
connection_policy.UseMultipleWriteLocations = True
connection_policy.PreferredLocations = [region]

client = cosmos_client.CosmosClient(self.account_endpoint, {
                                    'masterKey': self.account_key}, connection_policy,
documents.ConsistencyLevel.Session)
```

Manage consistency levels in Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains how to manage consistency levels in Azure Cosmos DB. You learn how to configure the default consistency level, override the default consistency, manually manage session tokens, and understand the Probabilistically Bounded Staleness (PBS) metric.

> **NOTE**
>
> This article has been updated to use the new Azure PowerShell Az module. You can still use the AzureRM module, which will continue to receive bug fixes until at least December 2020. To learn more about the new Az module and AzureRM compatibility, see Introducing the new Azure PowerShell Az module. For Az module installation instructions, see Install Azure PowerShell.

Configure the default consistency level

The default consistency level is the consistency level that clients use by default.

- Azure portal
- CLI
- PowerShell

To view or modify the default consistency level, sign in to the Azure portal. Find your Azure Cosmos account, and open the **Default consistency** pane. Select the level of consistency you want as the new default, and then select **Save**. The Azure portal also provides a visualization of different consistency levels with music notes.

Override the default consistency level

Clients can override the default consistency level that is set by the service. Consistency level can be set on a per request, which overrides the default consistency level set at the account level.

> **TIP**
> Consistency can only be **relaxed** at the request level. To move from weaker to stronger consistency, update the default consistency for the Cosmos account.

.NET SDK

- .NET SDK V2
- .NET SDK V3

```
// Override consistency at the client level
documentClient = new DocumentClient(new Uri(endpoint), authKey, connectionPolicy, ConsistencyLevel.Eventual);

// Override consistency at the request level via request options
RequestOptions requestOptions = new RequestOptions { ConsistencyLevel = ConsistencyLevel.Eventual };

var response = await client.CreateDocumentAsync(collectionUri, document, requestOptions);
```

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
CosmosAsyncClient client =
        new CosmosClientBuilder()
                .endpoint(HOST)
                .key(MASTER_KEY)
                .consistencyLevel(ConsistencyLevel.EVENTUAL)
                .buildAsyncClient();
```

Java V2 SDKs

- Async
- Sync

Async Java V2 SDK (Maven com.microsoft.azure::azure-cosmosdb)

```
// Override consistency at the client level
ConnectionPolicy policy = new ConnectionPolicy();

AsyncDocumentClient client =
        new AsyncDocumentClient.Builder()
                .withMasterKey(this.accountKey)
                .withServiceEndpoint(this.accountEndpoint)
                .withConsistencyLevel(ConsistencyLevel.Eventual)
                .withConnectionPolicy(policy).build();
```

Node.js/JavaScript/TypeScript SDK

```
// Override consistency at the client level
const client = new CosmosClient({
  /* other config... */
  consistencyLevel: ConsistencyLevel.Eventual
});

// Override consistency at the request level via request options
const { body } = await item.read({ consistencyLevel: ConsistencyLevel.Eventual });
```

Python SDK

```
# Override consistency at the client level
connection_policy = documents.ConnectionPolicy()
client = cosmos_client.CosmosClient(self.account_endpoint, {
                                    'masterKey': self.account_key}, connection_policy,
documents.ConsistencyLevel.Eventual)
```

Utilize session tokens

One of the consistency levels in Azure Cosmos DB is *Session* consistency. This is the default level applied to Cosmos accounts by default. When working with *Session* consistency, the client will use a session token internally with each read/query request to ensure that the set consistency level is maintained.

To manage session tokens manually, get the session token from the response and set them per request. If you don't need to manage session tokens manually, you don't need to use these samples. The SDK keeps track of session tokens automatically. If you don't set the session token manually, by default, the SDK uses the most recent session token.

.NET SDK

- .NET SDK V2
- .NET SDK V3

```
var response = await client.ReadDocumentAsync(
                UriFactory.CreateDocumentUri(databaseName, collectionName, "SalesOrder1"));
string sessionToken = response.SessionToken;

RequestOptions options = new RequestOptions();
options.SessionToken = sessionToken;
var response = await client.ReadDocumentAsync(
                UriFactory.CreateDocumentUri(databaseName, collectionName, "SalesOrder1"), options);
```

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
// Get session token from response
CosmosItemResponse<JsonNode> response = container.readItem(itemId, new PartitionKey(partitionKey),
JsonNode.class).block();
String sessionToken = response.getSessionToken();

// Resume the session by setting the session token on the RequestOptions
CosmosItemRequestOptions options = new CosmosItemRequestOptions();
options.setSessionToken(sessionToken);
CosmosItemResponse<JsonNode> response2 = container.readItem(itemId, new PartitionKey(partitionKey),
JsonNode.class).block();
```

Java V2 SDKs

- Async
- Sync

Async Java V2 SDK (Maven com.microsoft.azure::azure-cosmosdb)

```
// Get session token from response
RequestOptions options = new RequestOptions();
options.setPartitionKey(new PartitionKey(document.get("mypk")));
Observable<ResourceResponse<Document>> readObservable = client.readDocument(document.getSelfLink(), options);
readObservable.single()           // we know there will be one response
  .subscribe(
      documentResourceResponse -> {
          System.out.println(documentResourceResponse.getSessionToken());
      },
      error -> {
          System.err.println("an error happened: " + error.getMessage());
      });

// Resume the session by setting the session token on RequestOptions
RequestOptions options = new RequestOptions();
requestOptions.setSessionToken(sessionToken);
Observable<ResourceResponse<Document>> readObservable = client.readDocument(document.getSelfLink(), options);
```

Node.js/JavaScript/TypeScript SDK

```
// Get session token from response
const { headers, item } = await container.items.create({ id: "meaningful-id" });
const sessionToken = headers["x-ms-session-token"];

// Immediately or later, you can use that sessionToken from the header to resume that session.
const { body } = await item.read({ sessionToken });
```

Python SDK

```
// Get the session token from the last response headers
item = client.ReadItem(item_link)
session_token = client.last_response_headers["x-ms-session-token"]

// Resume the session by setting the session token on the options for the request
options = {
    "sessionToken": session_token
}
item = client.ReadItem(doc_link, options)
```

Monitor Probabilistically Bounded Staleness (PBS) metric

How eventual is eventual consistency? For the average case, can we offer staleness bounds with respect to version history and time. The **Probabilistically Bounded Staleness (PBS)** metric tries to quantify the probability of staleness and shows it as a metric. To view the PBS metric, go to your Azure Cosmos account in the Azure portal. Open the **Metrics** pane, and select the **Consistency** tab. Look at the graph named **Probability of strongly consistent reads based on your workload (see PBS)**.

Manage conflict resolution policies in Azure Cosmos DB

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

With multi-region writes, when multiple clients write to the same item, conflicts may occur. When a conflict occurs, you can resolve the conflict by using different conflict resolution policies. This article describes how to manage conflict resolution policies.

Create a last-writer-wins conflict resolution policy

These samples show how to set up a container with a last-writer-wins conflict resolution policy. The default path for last-writer-wins is the timestamp field or the `_ts` property. For SQL API, this may also be set to a user-defined path with a numeric type. In a conflict, the highest value wins. If the path isn't set or it's invalid, it defaults to `_ts`. Conflicts resolved with this policy do not show up in the conflict feed. This policy can be used by all APIs.

.NET SDK

- .NET SDK V2
- .NET SDK V3

```
DocumentCollection lwwCollection = await createClient.CreateDocumentCollectionIfNotExistsAsync(
  UriFactory.CreateDatabaseUri(this.databaseName), new DocumentCollection
  {
      Id = this.lwwCollectionName,
      ConflictResolutionPolicy = new ConflictResolutionPolicy
      {
          Mode = ConflictResolutionMode.LastWriterWins,
          ConflictResolutionPath = "/myCustomId",
      },
  });
```

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
ConflictResolutionPolicy policy = ConflictResolutionPolicy.createLastWriterWinsPolicy("/myCustomId");

CosmosContainerProperties containerProperties = new CosmosContainerProperties(container_id, partition_key);
containerProperties.setConflictResolutionPolicy(policy);
/* ...other container config... */
database.createContainerIfNotExists(containerProperties).block();
```

Java V2 SDKs

- Async Java V2 SDK
- Sync Java V2 SDK

Async Java V2 SDK (Maven com.microsoft.azure::azure-cosmosdb)

```
DocumentCollection collection = new DocumentCollection();
collection.setId(id);
ConflictResolutionPolicy policy = ConflictResolutionPolicy.createLastWriterWinsPolicy("/myCustomId");
collection.setConflictResolutionPolicy(policy);
DocumentCollection createdCollection = client.createCollection(databaseUri, collection,
null).toBlocking().value();
```

Node.js/JavaScript/TypeScript SDK

```
const database = client.database(this.databaseName);
const { container: lwwContainer } = await database.containers.createIfNotExists(
  {
    id: this.lwwContainerName,
    conflictResolutionPolicy: {
      mode: "LastWriterWins",
      conflictResolutionPath: "/myCustomId"
    }
  }
);
```

Python SDK

```
udp_collection = {
    'id': self.udp_collection_name,
    'conflictResolutionPolicy': {
        'mode': 'LastWriterWins',
        'conflictResolutionPath': '/myCustomId'
    }
}
udp_collection = self.try_create_document_collection(
    create_client, database, udp_collection)
```

Create a custom conflict resolution policy using a stored procedure

These samples show how to set up a container with a custom conflict resolution policy with a stored procedure to resolve the conflict. These conflicts don't show up in the conflict feed unless there's an error in your stored procedure. After the policy is created with the container, you need to create the stored procedure. The .NET SDK sample below shows an example. This policy is supported on Core (SQL) Api only.

Sample custom conflict resolution stored procedure

Custom conflict resolution stored procedures must be implemented using the function signature shown below. The function name does not need to match the name used when registering the stored procedure with the container but it does simplify naming. Here is a description of the parameters that must be implemented for this stored procedure.

- **incomingItem**: The item being inserted or updated in the commit that is generating the conflicts. Is null for delete operations.
- **existingItem**: The currently committed item. This value is non-null in an update and null for an insert or deletes.
- **isTombstone**: Boolean indicating if the incomingItem is conflicting with a previously deleted item. When true, existingItem is also null.
- **conflictingItems**: Array of the committed version of all items in the container that are conflicting with incomingItem on ID or any other unique index properties.

> **IMPORTANT**
> Just as with any stored procedure, a custom conflict resolution procedure can access any data with the same partition key and can perform any insert, update or delete operation to resolve conflicts.

This sample stored procedure resolves conflicts by selecting the lowest value from the `/myCustomId` path.

```
function resolver(incomingItem, existingItem, isTombstone, conflictingItems) {
  var collection = getContext().getCollection();

  if (!incomingItem) {
      if (existingItem) {

          collection.deleteDocument(existingItem._self, {}, function (err, responseOptions) {
              if (err) throw err;
          });
      }
  } else if (isTombstone) {
      // delete always wins.
  } else {
      if (existingItem) {
          if (incomingItem.myCustomId > existingItem.myCustomId) {
              return; // existing item wins
          }
      }

      var i;
      for (i = 0; i < conflictingItems.length; i++) {
          if (incomingItem.myCustomId > conflictingItems[i].myCustomId) {
              return; // existing conflict item wins
          }
      }

      // incoming item wins - clear conflicts and replace existing with incoming.
      tryDelete(conflictingItems, incomingItem, existingItem);
  }

  function tryDelete(documents, incoming, existing) {
      if (documents.length > 0) {
          collection.deleteDocument(documents[0]._self, {}, function (err, responseOptions) {
              if (err) throw err;

              documents.shift();
              tryDelete(documents, incoming, existing);
          });
      } else if (existing) {
          collection.replaceDocument(existing._self, incoming,
              function (err, documentCreated) {
                  if (err) throw err;
              });
      } else {
          collection.createDocument(collection.getSelfLink(), incoming,
              function (err, documentCreated) {
                  if (err) throw err;
              });
      }
  }
}
```

.NET SDK

- .NET SDK V2
- .NET SDK V3

```
DocumentCollection udpCollection = await createClient.CreateDocumentCollectionIfNotExistsAsync(
  UriFactory.CreateDatabaseUri(this.databaseName), new DocumentCollection
  {
      Id = this.udpCollectionName,
      ConflictResolutionPolicy = new ConflictResolutionPolicy
      {
          Mode = ConflictResolutionMode.Custom,
          ConflictResolutionProcedure = string.Format("dbs/{0}/colls/{1}/sprocs/{2}", this.databaseName,
this.udpCollectionName, "resolver"),
      },
  });

//Create the stored procedure
await clients[0].CreateStoredProcedureAsync(
UriFactory.CreateStoredProcedureUri(this.databaseName, this.udpCollectionName, "resolver"), new
StoredProcedure
{
    Id = "resolver",
    Body = File.ReadAllText(@"resolver.js")
});
```

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
ConflictResolutionPolicy policy = ConflictResolutionPolicy.createCustomPolicy("resolver");

CosmosContainerProperties containerProperties = new CosmosContainerProperties(container_id, partition_key);
containerProperties.setConflictResolutionPolicy(policy);
/* ...other container config... */
database.createContainerIfNotExists(containerProperties).block();
```

Java V2 SDKs

- Async Java V2 SDK
- Sync Java V2 SDK

Async Java V2 SDK (Maven com.microsoft.azure::azure-cosmosdb)

```
DocumentCollection collection = new DocumentCollection();
collection.setId(id);
ConflictResolutionPolicy policy = ConflictResolutionPolicy.createCustomPolicy("resolver");
collection.setConflictResolutionPolicy(policy);
DocumentCollection createdCollection = client.createCollection(databaseUri, collection,
null).toBlocking().value();
```

After your container is created, you must create the `resolver` stored procedure.

Node.js/JavaScript/TypeScript SDK

```
const database = client.database(this.databaseName);
const { container: udpContainer } = await database.containers.createIfNotExists(
  {
    id: this.udpContainerName,
    conflictResolutionPolicy: {
      mode: "Custom",
      conflictResolutionProcedure: `dbs/${this.databaseName}/colls/${
        this.udpContainerName
      }/sprocs/resolver`
    }
  }
);
```

After your container is created, you must create the `resolver` stored procedure.

Python SDK

```
udp_collection = {
    'id': self.udp_collection_name,
    'conflictResolutionPolicy': {
        'mode': 'Custom',
        'conflictResolutionProcedure': 'dbs/' + self.database_name + "/colls/" + self.udp_collection_name +
'/sprocs/resolver'
    }
}
udp_collection = self.try_create_document_collection(
    create_client, database, udp_collection)
```

After your container is created, you must create the `resolver` stored procedure.

Create a custom conflict resolution policy

These samples show how to set up a container with a custom conflict resolution policy. These conflicts show up in the conflict feed.

.NET SDK

- .NET SDK V2
- .NET SDK V3

```
DocumentCollection manualCollection = await createClient.CreateDocumentCollectionIfNotExistsAsync(
  UriFactory.CreateDatabaseUri(this.databaseName), new DocumentCollection
  {
      Id = this.manualCollectionName,
      ConflictResolutionPolicy = new ConflictResolutionPolicy
      {
          Mode = ConflictResolutionMode.Custom,
      },
  });
```

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
ConflictResolutionPolicy policy = ConflictResolutionPolicy.createCustomPolicy();

CosmosContainerProperties containerProperties = new CosmosContainerProperties(container_id, partition_key);
containerProperties.setConflictResolutionPolicy(policy);
/* ...other container config... */
database.createContainerIfNotExists(containerProperties).block();
```

Java V2 SDKs

- Async Java V2 SDK
- Sync Java V2 SDK

Async Java V2 SDK (Maven com.microsoft.azure::azure-cosmosdb)

```
DocumentCollection collection = new DocumentCollection();
collection.setId(id);
ConflictResolutionPolicy policy = ConflictResolutionPolicy.createCustomPolicy();
collection.setConflictResolutionPolicy(policy);
DocumentCollection createdCollection = client.createCollection(databaseUri, collection,
null).toBlocking().value();
```

Node.js/JavaScript/TypeScript SDK

```
const database = client.database(this.databaseName);
const {
  container: manualContainer
} = await database.containers.createIfNotExists({
  id: this.manualContainerName,
  conflictResolutionPolicy: {
    mode: "Custom"
  }
});
```

Python SDK

```
database = client.ReadDatabase("dbs/" + self.database_name)
manual_collection = {
    'id': self.manual_collection_name,
    'conflictResolutionPolicy': {
        'mode': 'Custom'
    }
}
manual_collection = client.CreateContainer(database['_self'], collection)
```

Read from conflict feed

These samples show how to read from a container's conflict feed. Conflicts show up in the conflict feed only if they weren't resolved automatically or if using a custom conflict policy.

.NET SDK

- .NET SDK V2
- .NET SDK V3

```
FeedResponse<Conflict> conflicts = await delClient.ReadConflictFeedAsync(this.collectionUri);
```

Java V2 SDKs

- Async Java V2 SDK
- Sync Java V2 SDK

Async Java V2 SDK (Maven com.microsoft.azure::azure-cosmosdb)

```
FeedResponse<Conflict> response = client.readConflicts(this.manualCollectionUri, null)
                    .first().toBlocking().single();
for (Conflict conflict : response.getResults()) {
    /* Do something with conflict */
}
```

Node.js/JavaScript/TypeScript SDK

```
const container = client
  .database(this.databaseName)
  .container(this.lwwContainerName);

const { result: conflicts } = await container.conflicts.readAll().toArray();
```

Python

```
conflicts_iterator = iter(client.ReadConflicts(self.manual_collection_link))
conflict = next(conflicts_iterator, None)
while conflict:
    # Do something with conflict
    conflict = next(conflicts_iterator, None)
```

Convert session token formats in .NET SDK

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains how to convert between different session token formats to ensure compatibility between SDK versions.

> **NOTE**
>
> By default, the SDK keeps track of the session token automatically and it will use the most recent session token. For more information, please visit Utilize session tokens. The instructions in this article only apply with the following conditions:
>
> - Your Azure Cosmos DB account uses Session consistency.
> - You are managing the session tokens are manually.
> - You are using multiple versions of the SDK at the same time.

Session token formats

There are two session token formats: **simple** and **vector**. These two formats are not interchangeable so, the format should be converted when passing to the client application with different versions.

- The **simple** session token format is used by the .NET SDK V1 (Microsoft.Azure.DocumentDB -version 1.x)
- The **vector** session token format is used by the .NET SDK V2 (Microsoft.Azure.DocumentDB -version 2.x)

Simple session token

A simple session token has this format: `{pkrangeid}:{globalLSN}`

Vector session token

A vector session token has the following format:

```
{pkrangeid}:{Version}#{GlobalLSN}#{RegionId1}={LocalLsn1}#{RegionId2}={LocalLsn2}....#{RegionIdN}={LocalLsnN}
```

Convert to Simple session token

To pass a session token to client using .NET SDK V1, use a **simple** session token format. For example, use the following sample code to convert it.

```
private static readonly char[] SegmentSeparator = (new[] { '#' });
private static readonly char[] PkRangeSeparator = (new[] { ':' });

// sessionTokenToConvert = session token from previous response
string[] items = sessionTokenToConvert.Split(PkRangeSeparator, StringSplitOptions.RemoveEmptyEntries);
string[] sessionTokenSegments = items[1].Split(SessionTokenHelpers.SegmentSeparator,
StringSplitOptions.RemoveEmptyEntries);

string sessionTokenInSimpleFormat;

if (sessionTokenSegments.Length == 1)
{
    // returning the same token since it already has the correct format
    sessionTokenInSimpleFormat = sessionTokenToConvert;
}
else
{
    long version = 0;
    long globalLSN = 0;

    if (!long.TryParse(sessionTokenSegments[0], out version)
        || !long.TryParse(sessionTokenSegments[1], out globalLSN))
    {
        throw new ArgumentException("Invalid session token format", sessionTokenToConvert);
    }

    sessionTokenInSimpleFormat = string.Format("{0}:{1}", items[0], globalLSN);
}
```

Convert to Vector session token

To pass a session token to client using .NET SDK V2, use the **vector** session token format. For example, use the following sample code to convert it.

```
private static readonly char[] SegmentSeparator = (new[] { '#' });
private static readonly char[] PkRangeSeparator = (new[] { ':' });

// sessionTokenToConvert = session token from previous response
string[] items = sessionTokenToConvert.Split(PkRangeSeparator, StringSplitOptions.RemoveEmptyEntries);
string[] sessionTokenSegments = items[1].Split(SegmentSeparator, StringSplitOptions.RemoveEmptyEntries);

string sessionTokenInVectorFormat;

if (sessionTokenSegments.Length == 1)
{
    long globalLSN = 0;
    if (long.TryParse(sessionTokenSegments[0], out globalLSN))
    {
        sessionTokenInVectorFormat = string.Format("{0}:-2#{1}", items[0], globalLSN);
    }
    else
    {
        throw new ArgumentException("Invalid session token format", sessionTokenToConvert);
    }
}
else
{
    // returning the same token since it already has the correct format
    sessionTokenInVectorFormat = sessionTokenToConvert;
}
```

Provision standard (manual) throughput on an Azure Cosmos container - SQL API

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains how to provision standard (manual) throughput on a container in Azure Cosmos DB SQL API. You can provision throughput on a single container, or provision throughput on a database and share it among the containers within the database. You can provision throughput on a container using Azure portal, Azure CLI, or Azure Cosmos DB SDKs.

If you are using a different API, see API for MongoDB, Cassandra API, Gremlin API articles to provision the throughput.

Azure portal

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account, or select an existing Azure Cosmos account.
3. Open the **Data Explorer** pane, and select **New Container**. Next, provide the following details:
   - Indicate whether you are creating a new database or using an existing one.
   - Enter a Container ID.
   - Enter a partition key value (for example, `/ItemID`).
   - Enter a throughput that you want to provision (for example, 1000 RUs).
   - Select **OK**.

Azure CLI or PowerShell

To create a container with dedicated throughput see,

- Create a container using Azure CLI
- Create a container using PowerShell

.NET SDK

> **NOTE**
>
> Use the Cosmos SDKs for SQL API to provision throughput for all Cosmos DB APIs, except Cassandra and MongoDB API.

- .NET SDK V2
- .NET SDK V3

```
// Create a container with a partition key and provision throughput of 400 RU/s
DocumentCollection myCollection = new DocumentCollection();
myCollection.Id = "myContainerName";
myCollection.PartitionKey.Paths.Add("/myPartitionKey");

await client.CreateDocumentCollectionAsync(
    UriFactory.CreateDatabaseUri("myDatabaseName"),
    myCollection,
    new RequestOptions { OfferThroughput = 400 });
```

JavaScript SDK

```
// Create a new Client
const client = new CosmosClient({ endpoint, key });

// Create a database
const { database } = await client.databases.createIfNotExists({ id: "databaseId" });

// Create a container with the specified throughput
const { resource } = await database.containers.createIfNotExists({
id: "containerId",
throughput: 1000
});

// To update an existing container or databases throughput, you need to user the offers API
// Get all the offers
const { resources: offers } = await client.offers.readAll().fetchAll();

// Find the offer associated with your container or the database
const offer = offers.find((_offer) => _offer.offerResourceId === resource._rid);

// Change the throughput value
offer.content.offerThroughput = 2000;

// Replace the offer.
await client.offer(offer.id).replace(offer);
```

Next steps

Provision standard (manual) throughput on a database in Azure Cosmos DB - SQL API

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains how to provision standard (manual) throughput on a database in Azure Cosmos DB SQL API. You can provision throughput for a single container, or for a database and share the throughput among the containers within it. To learn when to use container level and database level throughput, see the Use cases for provisioning throughput on containers and databases article. You can provision database level throughput by using the Azure portal or Azure Cosmos DB SDKs.

If you are using a different API, see API for MongoDB, Cassandra API, Gremlin API articles to provision the throughput.

Provision throughput using Azure portal

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account, or select an existing Azure Cosmos account.
3. Open the **Data Explorer** pane, and select **New Database**. Provide the following details:
   - Enter a database ID.
   - Select the **Provision database throughput** option.
   - Enter a throughput (for example, 1000 RUs).
   - Select **OK**.

Provision throughput using Azure CLI or PowerShell

To create a database with shared throughput see,

- Create a database using Azure CLI
- Create a database using PowerShell

Provision throughput using .NET SDK

> **NOTE**
>
> You can use Azure Cosmos SDKs for SQL API to provision throughput for all APIs. You can optionally use the following example for Cassandra API as well.

- .NET SDK V2
- .NET SDK V3

```
//set the throughput for the database
RequestOptions options = new RequestOptions
{
    OfferThroughput = 500
};

//create the database
await client.CreateDatabaseIfNotExistsAsync(
    new Database {Id = databaseName},
    options);
```

Next steps

See the following articles to learn about provisioned throughput in Azure Cosmos DB:

- Globally scale provisioned throughput
- Provision throughput on containers and databases
- How to provision standard (manual) throughput for a container
- How to provision autoscale throughput for a container
- Request units and throughput in Azure Cosmos DB

Provision autoscale throughput on database or container in Azure Cosmos DB - SQL API

11/2/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains how to provision autoscale throughput on a database or container (collection, graph, or table) in Azure Cosmos DB SQL API. You can enable autoscale on a single container, or provision autoscale throughput on a database and share it among all the containers in the database.

If you are using a different API, see API for MongoDB, Cassandra API, Gremlin API articles to provision the throughput.

Azure portal

Create new database or container with autoscale

1. Sign in to the Azure portal or the Azure Cosmos DB explorer.
2. Navigate to your Azure Cosmos DB account and open the **Data Explorer** tab.
3. Select **New Container.** Enter a name for your database, container, and a partition key. Under **Throughput**, select the **autoscale** option, and set the maximum throughput (RU/s) that you want the database or container to scale to.

4. Select **OK**.

To provision autoscale on shared throughput database, select the **Provision database throughput** option when creating a new database.

Enable autoscale on existing database or container

> **IMPORTANT**
>
> In the current release, the Azure portal is the only way to migrate between autoscale and standard (manual) provisioned throughput.

1. Sign in to the Azure portal or the Azure Cosmos DB explorer.
2. Navigate to your Azure Cosmos DB account and open the **Data Explorer** tab.
3. Select **Scale and Settings** for your container, or **Scale** for your database.
4. Under **Scale**, select the **Autoscale** option and **Save**.

> **NOTE**
>
> When you enable autoscale on an existing database or container, the starting value for max RU/s is determined by the system, based on your current manual provisioned throughput settings and storage. After the operation completes, you can change the max RU/s if needed. Learn more.

Azure Cosmos DB .NET V3 SDK

Use version 3.9 or higher of the Azure Cosmos DB .NET SDK for SQL API to manage autoscale resources.

> **IMPORTANT**
>
> You can use the .NET SDK to create new autoscale resources. The SDK does not support migrating between autoscale and standard (manual) throughput. The migration scenario is currently supported in only the Azure portal.

Create database with shared throughput

```
// Create instance of CosmosClient
CosmosClient cosmosClient = new CosmosClient(Endpoint, PrimaryKey);

// Autoscale throughput settings
ThroughputProperties autoscaleThroughputProperties = ThroughputProperties.CreateAutoscaleThroughput(4000);
//Set autoscale max RU/s

//Create the database with autoscale enabled
database = await cosmosClient.CreateDatabaseAsync(DatabaseName, throughputProperties:
autoscaleThroughputProperties);
```

Create container with dedicated throughput

```
// Get reference to database that container will be created in
Database database = await cosmosClient.GetDatabase("DatabaseName");

// Container and autoscale throughput settings
ContainerProperties autoscaleContainerProperties = new ContainerProperties("ContainerName",
"/partitionKey");
ThroughputProperties autoscaleThroughputProperties = ThroughputProperties.CreateAutoscaleThroughput(4000);
//Set autoscale max RU/s

// Create the container with autoscale enabled
container = await database.CreateContainerAsync(autoscaleContainerProperties,
autoscaleThroughputProperties);
```

Read the current throughput (RU/s)

```
// Get a reference to the resource
Container container = cosmosClient.GetDatabase("DatabaseName").GetContainer("ContainerName");

// Read the throughput on a resource
ThroughputProperties autoscaleContainerThroughput = await container.ReadThroughputAsync(requestOptions:
null);

// The autoscale max throughput (RU/s) of the resource
int? autoscaleMaxThroughput = autoscaleContainerThroughput.AutoscaleMaxThroughput;

// The throughput (RU/s) the resource is currently scaled to
int? currentThroughput = autoscaleContainerThroughput.Throughput;
```

Change the autoscale max throughput (RU/s)

```
// Change the autoscale max throughput (RU/s)
await
container.ReplaceThroughputAsync(ThroughputProperties.CreateAutoscaleThroughput(newAutoscaleMaxThroughput));
```

Azure Cosmos DB Java V4 SDK

You can use version 4.0 or higher of the Azure Cosmos DB Java SDK for SQL API to manage autoscale resources.

> **IMPORTANT**
>
> You can use the Java SDK to create new autoscale resources. The SDK does not support migrating between autoscale and standard (manual) throughput. The migration scenario is currently supported in only the Azure portal.

Create database with shared throughput

- Async

- Sync

```
// Create instance of CosmosClient
CosmosAsyncClient client = new CosmosClientBuilder()
    .setEndpoint(HOST)
    .setKey(MASTER)
    .setConnectionPolicy(CONNECTIONPOLICY)
    .buildAsyncClient();

// Autoscale throughput settings
ThroughputProperties autoscaleThroughputProperties = ThroughputProperties.createAutoscaledThroughput(4000);
//Set autoscale max RU/s

//Create the database with autoscale enabled
CosmosAsyncDatabase database = client.createDatabase(databaseName,
autoscaleThroughputProperties).block().getDatabase();
```

Create container with dedicated throughput

- Async
- Sync

```
// Get reference to database that container will be created in
CosmosAsyncDatabase database = client.createDatabase("DatabaseName").block().getDatabase();

// Container and autoscale throughput settings
CosmosContainerProperties autoscaleContainerProperties = new CosmosContainerProperties("ContainerName",
"/partitionKey");
ThroughputProperties autoscaleThroughputProperties = ThroughputProperties.createAutoscaledThroughput(4000);
//Set autoscale max RU/s

// Create the container with autoscale enabled
CosmosAsyncContainer container = database.createContainer(autoscaleContainerProperties,
autoscaleThroughputProperties, new CosmosContainerRequestOptions())
                                .block()
                                .getContainer();
```

Read the current throughput (RU/s)

- Async
- Sync

```
// Get a reference to the resource
CosmosAsyncContainer container = client.getDatabase("DatabaseName").getContainer("ContainerName");

// Read the throughput on a resource
ThroughputProperties autoscaleContainerThroughput = container.readThroughput().block().getProperties();

// The autoscale max throughput (RU/s) of the resource
int autoscaleMaxThroughput = autoscaleContainerThroughput.getAutoscaleMaxThroughput();

// The throughput (RU/s) the resource is currently scaled to
int currentThroughput = autoscaleContainerThroughput.Throughput;
```

Change the autoscale max throughput (RU/s)

- Async
- Sync

```
// Change the autoscale max throughput (RU/s)
container.replaceThroughput(ThroughputProperties.createAutoscaledThroughput(newAutoscaleMaxThroughput)).bloc
k();
```

Azure Resource Manager

Azure Resource Manager templates can be used to provision autoscale throughput on database or container-level resources for all Azure Cosmos DB APIs. See Azure Resource Manager templates for Azure Cosmos DB for samples.

Azure CLI

Azure CLI can be used to provision autoscale throughput on a database or container-level resources for all Azure Cosmos DB APIs. For samples see Azure CLI Samples for Azure Cosmos DB.

Azure PowerShell

Azure PowerShell can be used to provision autoscale throughput on a database or container-level resources for all Azure Cosmos DB APIs. For samples see Azure PowerShell samples for Azure Cosmos DB.

- Learn about the benefits of provisioned throughput with autoscale.
- Learn how to choose between manual and autoscale throughput.
- Review the autoscale FAQ.

Estimate RU/s using the Azure Cosmos DB capacity planner

12/4/2020 • 6 minutes to read • Edit Online

APPLIES TO: SQL API

Configuring your Azure Cosmos databases and containers with the right amount of provisioned throughput, or Request Units (RU/s), for your workload is essential to optimizing cost and performance. This article describes how to use the Azure Cosmos DB capacity planner to get an estimate of the required RU/s and cost of your workload.

How to estimate throughput and cost with Azure Cosmos DB capacity planner

The capacity planner can be used in two modes.

MODE	DESCRIPTION
Basic	Provides a quick, high-level RU/s and cost estimate. This mode assumes the default Azure Cosmos DB settings for indexing policy, consistency, and other parameters. Use basic mode for a quick, high-level estimate when you are evaluating a potential workload to run on Azure Cosmos DB.
Advanced	Provides a more detailed RU/s and cost estimate, with the ability to tune additional settings — indexing policy, consistency level, and other parameters that affect the cost and throughput. Use advanced mode when you are estimating RU/s for a new project or want a more detailed estimate.

Estimate provisioned throughput and cost using basic mode

To get a quick estimate for your workload using the basic mode, navigate to the capacity planner. Enter in the following parameters based on your workload:

INPUT	DESCRIPTION
Number of regions	Azure Cosmos DB is available in all Azure regions. Select the number of regions required for your workload. You can associate any number of regions with your Cosmos account. See global distribution in Azure Cosmos DB for more details.

INPUT	DESCRIPTION
Multi-region writes	If you enable multi-region writes, your application can read and write to any Azure region. If you disable multi-region writes, your application can write data to a single region. Enable multi-region writes if you expect to have an active-active workload that requires low latency writes in different regions. For example, an IOT workload that writes data to the database at high volumes in different regions. Multi-region writes guarantees 99.999% read and write availability. Multi-region writes require more throughput when compared to the single write regions. To learn more, see how RUs are different for single and multiple-write regions article.
Total data stored (per region)	Total estimated data stored in GB in a single region.
Item size	The estimated size of the data item (e.g. document), ranging from 1 KB to 2 MB.
Reads/sec per region	Number of reads expected per second.
Writes/sec per region	Number of writes expected per second.

After filling the required details, select **Calculate**. The **Cost Estimate** tab shows the total cost for storage and provisioned throughput. You can expand the **Show Details** link in this tab to get the breakdown of the throughput required for read and write requests. Each time you change the value of any field, select **Calculate** to re-calculate the estimated cost.

Estimate provisioned throughput and cost using advanced mode

Advanced mode allows you to provide more settings that impact the RU/s estimate. To use this option, navigate to the capacity planner and sign in to the tool with an account you use for Azure. The sign-in option is available at

the right-hand corner.

After you sign in, you can see additional fields compared to the fields in basic mode. Enter the additional parameters based on your workload.

INPUT	DESCRIPTION
API	Azure Cosmos DB is a multi-model and multi-API service. For new workloads, select SQL (Core) API.
Number of regions	Azure Cosmos DB is available in all Azure regions. Select the number of regions required for your workload. You can associate any number of regions with your Cosmos account. See global distribution in Azure Cosmos DB for more details.
Multi-region writes	If you enable multi-region writes, your application can read and write to any Azure region. If you disable multi-region writes, your application can write data to a single region. Enable multi-region writes if you expect to have an active-active workload that requires low latency writes in different regions. For example, an IOT workload that writes data to the database at high volumes in different regions. Multi-region writes guarantees 99.999% read and write availability. Multi-region writes require more throughput when compared to the single write regions. To learn more, see how RUs are different for single and multiple-write regions article.
Default consistency	Azure Cosmos DB supports 5 consistency levels, to allow developers to balance the tradeoff between consistency, availability, and latency tradeoffs. To learn more, see the consistency levels article. By default, Azure Cosmos DB uses session consistency, which guarantees the ability to read your own writes in a session. Choosing strong or bounded staleness will require double the required RU/s for reads, when compared to session, consistent prefix, and eventual consistency. Strong consistency with multi-region writes is not supported and will automatically default to single-region writes with strong consistency.
Indexing policy	By default, Azure Cosmos DB indexes all properties in all items for flexible and efficient queries (maps to the **Automatic** indexing policy). If you choose **off**, none of the properties are indexed. This results in the lowest RU charge for writes. Select **off** policy if you expect to only do point reads (key value lookups) and/or writes, and no queries. Custom indexing policy allows you to include or exclude specific properties from the index for lower write throughput and storage. To learn more, see indexing policy and sample indexing policies articles.
Total data stored (per region)	Total estimated data stored in GB in a single region.

INPUT	DESCRIPTION
Workload mode	Select **Steady** if your workload volume is constant. Select **Variable** if your workload volume changes over time. For example, during a specific day or a month. The following settings are available if you choose the variable workload option: • Percentage of time at peak: Percentage of time in a month where your workload requires peak (highest) throughput. For example, if you have a workload that has high activity during 9am – 6pm weekday business hours, then the percentage of time at peak is: 45 hours at peak / 730 hours / month = ~6%. • Reads/sec per region at peak - Number of reads expected per second at peak. • Writes/sec per region at peak – Number of writes expected per second at peak. • Reads/sec per region off peak – Number of reads expected per second during off peak. • Writes/sec per region off peak – Number of writes expected per second during off peak. With peak and off-peak intervals, you can optimize your cost by programmatically scaling your provisioned throughput up and down accordingly.
Item size	The size of the data item (e.g. document), ranging from 1 KB to 2 MB. You can also **Upload sample (JSON)** document for a more accurate estimate. If your workload has multiple types of items (with different JSON content) in the same container, you can upload multiple JSON documents and get the estimate. Use the **Add new item** button to add multiple sample JSON documents.

You can also use the **Save Estimate** button to download a CSV file containing the current estimate.

The prices shown in the Azure Cosmos DB capacity planner are estimates based on the public pricing rates for throughput and storage. All prices are shown in US dollars. Refer to the Azure Cosmos DB pricing page to see all rates by region.

Estimating throughput for queries

The Azure Cosmos capacity calculator assumes point reads (a read of a single item, e.g. document, by ID and partition key value) and writes for the workload. To estimate the throughput needed for queries, run your query on a representative data set in a Cosmos container and obtain the RU charge. Multiply the RU charge by the number of queries that you anticipate to run per second to get the total RU/s required.

For example, if your workload requires a query, `SELECT * FROM c WHERE c.id = 'Alice'` that is run 100 times per second, and the RU charge of the query is 10 RUs, you will need 100 query / sec * 10 RU / query = 1000 RU/s in total to serve these requests. Add these RU/s to the RU/s required for any reads or writes happening in your workload.

Next steps

- Learn more about Azure Cosmos DB's pricing model.
- Create a new Cosmos account, database, and container.
- Learn how to optimize provisioned throughput cost.
- Learn how to optimize cost with reserved capacity.

Scale Azure Cosmos DB throughput by using Azure Functions Timer trigger

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The performance of an Azure Cosmos account is based on the amount of provisioned throughput expressed in Request Units per second (RU/s). The provisioning is at a second granularity and is billed based upon the highest RU/s per hour. This provisioned capacity model enables the service to provide a predictable and consistent throughput, guaranteed low latency, and high availability. Most production workloads these features. However, in development and testing environments where Azure Cosmos DB is only used during working hours, you can scale up the throughput in the morning and scale back down in the evening after working hours.

You can set the throughput via Azure Resource Manager Templates, Azure CLI, and PowerShell, for Core (SQL) API accounts, or by using the language-specific Azure Cosmos DB SDKs. The benefit of using Resource Manager Templates, Azure CLI or PowerShell is that they support all Azure Cosmos DB model APIs.

Throughput scheduler sample project

To simplify the process to scale Azure Cosmos DB on a schedule we've created a sample project called Azure Cosmos throughput scheduler. This project is an Azure Functions app with two timer triggers- "ScaleUpTrigger" and "ScaleDownTrigger". The triggers run a PowerShell script that sets the throughput on each resource as defined in the `resources.json` file in each trigger. The ScaleUpTrigger is configured to run at 8 AM UTC and the ScaleDownTrigger is configured to run at 6 PM UTC and these times can be easily updated within the `function.json` file for each trigger.

You can clone this project locally, modify it to specify the Azure Cosmos DB resources to scale up and down and the schedule to run. Later you can deploy it in an Azure subscription and secure it using managed service identity with Azure role-based access control (Azure RBAC) permissions with the "Azure Cosmos DB operator" role to set throughput on your Azure Cosmos accounts.

Next Steps

- Learn more and download the sample from Azure Cosmos DB throughput scheduler.

Find the request unit charge for operations executed in Azure Cosmos DB SQL API

11/2/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB supports many APIs, such as SQL, MongoDB, Cassandra, Gremlin, and Table. Each API has its own set of database operations. These operations range from simple point reads and writes to complex queries. Each database operation consumes system resources based on the complexity of the operation.

The cost of all database operations is normalized by Azure Cosmos DB and is expressed by Request Units (or RUs, for short). You can think of RUs as a performance currency abstracting the system resources such as CPU, IOPS, and memory that are required to perform the database operations supported by Azure Cosmos DB. No matter which API you use to interact with your Azure Cosmos container, costs are always measured by RUs. Whether the database operation is a write, point read, or query, costs are always measured in RUs. To learn more, see the request units and it's considerations article.

This article presents the different ways you can find the request unit (RU) consumption for any operation executed against a container in Azure Cosmos DB SQL API. If you are using a different API, see API for MongoDB, Cassandra API, Gremlin API, and Table API articles to find the RU/s charge.

Currently, you can measure this consumption only by using the Azure portal or by inspecting the response sent back from Azure Cosmos DB through one of the SDKs. If you're using the SQL API, you have multiple options for finding the RU consumption for an operation against an Azure Cosmos container.

Use the Azure portal

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account and feed it with data, or selectan existing Azure Cosmos account that already contains data.
3. Go to the **Data Explorer** pane, and then select the container you want to work on.
4. Select **New SQL Query**.
5. Enter a valid query, and then select **Execute Query**.
6. Select **Query Stats** to display the actual request charge for the request you executed.

Use the .NET SDK

- .NET SDK V2
- .NET SDK V3

Objects that are returned from the .NET SDK v2 expose a `RequestCharge` property:

```
ResourceResponse<Document> fetchDocumentResponse = await client.ReadDocumentAsync(
    UriFactory.CreateDocumentUri("database", "container", "itemId"),
    new RequestOptions
    {
        PartitionKey = new PartitionKey("partitionKey")
    });
var requestCharge = fetchDocumentResponse.RequestCharge;

StoredProcedureResponse<string> storedProcedureCallResponse = await
client.ExecuteStoredProcedureAsync<string>(
    UriFactory.CreateStoredProcedureUri("database", "container", "storedProcedureId"),
    new RequestOptions
    {
        PartitionKey = new PartitionKey("partitionKey")
    });
requestCharge = storedProcedureCallResponse.RequestCharge;

IDocumentQuery<dynamic> query = client.CreateDocumentQuery(
    UriFactory.CreateDocumentCollectionUri("database", "container"),
    "SELECT * FROM c",
    new FeedOptions
    {
        PartitionKey = new PartitionKey("partitionKey")
    }).AsDocumentQuery();
while (query.HasMoreResults)
{
    FeedResponse<dynamic> queryResponse = await query.ExecuteNextAsync<dynamic>();
    requestCharge = queryResponse.RequestCharge;
}
```

Use the Java SDK

Objects that are returned from the Java SDK expose a `getRequestCharge()` method:

```
RequestOptions requestOptions = new RequestOptions();
requestOptions.setPartitionKey(new PartitionKey("partitionKey"));

Observable<ResourceResponse<Document>> readDocumentResponse =
client.readDocument(String.format("/dbs/%s/colls/%s/docs/%s", "database", "container", "itemId"),
requestOptions);
readDocumentResponse.subscribe(result -> {
    double requestCharge = result.getRequestCharge();
});

Observable<StoredProcedureResponse> storedProcedureResponse =
client.executeStoredProcedure(String.format("/dbs/%s/colls/%s/sprocs/%s", "database", "container",
"storedProcedureId"), requestOptions, null);
storedProcedureResponse.subscribe(result -> {
    double requestCharge = result.getRequestCharge();
});

FeedOptions feedOptions = new FeedOptions();
feedOptions.setPartitionKey(new PartitionKey("partitionKey"));

Observable<FeedResponse<Document>> feedResponse = client
    .queryDocuments(String.format("/dbs/%s/colls/%s", "database", "container"), "SELECT * FROM c",
feedOptions);
feedResponse.forEach(result -> {
    double requestCharge = result.getRequestCharge();
});
```

For more information, see Quickstart: Build a Java application by using an Azure Cosmos DB SQL API account.

Use the Node.js SDK

Objects that are returned from the Node.js SDK expose a `headers` subobject that maps all the headers returned by the underlying HTTP API. The request charge is available under the `x-ms-request-charge` key:

```
const item = await client
    .database('database')
    .container('container')
    .item('itemId', 'partitionKey')
    .read();
var requestCharge = item.headers['x-ms-request-charge'];

const storedProcedureResult = await client
    .database('database')
    .container('container')
    .storedProcedure('storedProcedureId')
    .execute({
        partitionKey: 'partitionKey'
    });
requestCharge = storedProcedureResult.headers['x-ms-request-charge'];

const query = client.database('database')
    .container('container')
    .items
    .query('SELECT * FROM c', {
        partitionKey: 'partitionKey'
    });
while (query.hasMoreResults()) {
    var result = await query.executeNext();
    requestCharge = result.headers['x-ms-request-charge'];
}
```

For more information, see Quickstart: Build a Node.js app by using an Azure Cosmos DB SQL API account.

Use the Python SDK

The `CosmosClient` object from the Python SDK exposes a `last_response_headers` dictionary that maps all the headers returned by the underlying HTTP API for the last operation executed. The request charge is available under the `x-ms-request-charge` key:

```
response = client.ReadItem(
    'dbs/database/colls/container/docs/itemId', {'partitionKey': 'partitionKey'})
request_charge = client.last_response_headers['x-ms-request-charge']

response = client.ExecuteStoredProcedure(
    'dbs/database/colls/container/sprocs/storedProcedureId', None, {'partitionKey': 'partitionKey'})
request_charge = client.last_response_headers['x-ms-request-charge']
```

For more information, see Quickstart: Build a Python app by using an Azure Cosmos DB SQL API account.

Create a container in Azure Cosmos DB SQL API

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains the different ways to create an container in Azure Cosmos DB SQL API. It shows how to create a container using the Azure portal, Azure CLI, PowerShell, or supported SDKs. This article demonstrates how to create a container, specify the partition key, and provision throughput.

This article explains the different ways to create a container in Azure Cosmos DB SQL API. If you are using a different API, see API for MongoDB, Cassandra API, Gremlin API, and Table API articles to create the container.

> **NOTE**
>
> When creating containers, make sure you don't create two containers with the same name but different casing. That's because some parts of the Azure platform are not case-sensitive, and this can result in confusion/collision of telemetry and actions on containers with such names.

Create a container using Azure portal

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account, or select an existing account.
3. Open the **Data Explorer** pane, and select **New Container**. Next, provide the following details:
   - Indicate whether you are creating a new database or using an existing one.
   - Enter a container ID.
   - Enter a partition key.
   - Enter a throughput to be provisioned (for example, 1000 RUs).
   - Select **OK**.

Create a container using Azure CLI

Create a container with Azure CLI. For a listing of all Azure CLI samples across all Azure Cosmos DB APIs see, Azure CLI samples for Azure Cosmos DB.

Create a container using PowerShell

Create a container with PowerShell. For a listing of all PowerShell samples across all Azure Cosmos DB APIs see, PowerShell Samples

Create a container using .NET SDK

If you encounter timeout exception when creating a collection, do a read operation to validate if the collection was created successfully. The read operation throws an exception until the collection create operation is successful. For the list of status codes supported by the create operation see the HTTP Status Codes for Azure Cosmos DB article.

```
// Create a container with a partition key and provision 1000 RU/s throughput.
DocumentCollection myCollection = new DocumentCollection();
myCollection.Id = "myContainerName";
myCollection.PartitionKey.Paths.Add("/myPartitionKey");

await client.CreateDocumentCollectionAsync(
    UriFactory.CreateDatabaseUri("myDatabaseName"),
    myCollection,
    new RequestOptions { OfferThroughput = 1000 });
```

Create containers with large partition key

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB uses hash-based partitioning scheme to achieve horizontal scaling of data. All Azure Cosmos containers created before May 3 2019 use a hash function that computes hash based on the first 100 bytes of the partition key. If there are multiple partition keys that have the same first 100 bytes, then those logical partitions are considered as the same logical partition by the service. This can lead to issues like partition size quota being incorrect, and unique indexes being applied across the partition keys. Large partition keys are introduced to solve this issue. Azure Cosmos DB now supports large partition keys with values up to 2 KB.

Large partition keys are supported by using the functionality of an enhanced version of the hash function, which can generate a unique hash from large partition keys up to 2 KB. This hash version is also recommended for scenarios with high partition key cardinality irrespective of the size of the partition key. A partition key cardinality is defined as the number of unique logical partitions, for example in the order of ~30000 logical partitions in a container. This article describes how to create a container with a large partition key using the Azure portal and different SDKs.

Create a large partition key (Azure portal)

To create a large partition key, when you create a new container using the Azure portal, check the **My partition key is larger than 100-bytes** option. Unselect the checkbox if you don't need large partition keys or if you have applications running on SDKs version older than 1.18.

Create a large partition key (PowerShell)

To create a container with large partition key support see,

- Create an Azure Cosmos container with a large partition key size

Create a large partition key (.Net SDK)

To create a container with a large partition key using the .NET SDK, specify the `PartitionKeyDefinitionVersion.V2` property. The following example shows how to specify the Version property within the PartitionKeyDefinition object and set it to PartitionKeyDefinitionVersion.V2.

- .NET SDK V3
- .NET SDK V2

```
await database.CreateContainerAsync(
    new ContainerProperties(collectionName, $"/longpartitionkey")
    {
        PartitionKeyDefinitionVersion = PartitionKeyDefinitionVersion.V2,
    })
```

Supported SDK versions

The Large partition keys are supported with the following minimum versions of SDKs:

SDK TYPE	MINIMUM VERSION
.Net	1.18
Java sync	2.4.0
Java Async	2.5.0
REST API	version higher than `2017-05-03` by using the `x-ms-version` request header.
Resource Manager template	version 2 by using the `"version":2` property within the `partitionKey` object.

Currently, you cannot use containers with large partition key within in Power BI and Azure Logic Apps. You can use containers without a large partition key from these applications.

Query an Azure Cosmos container

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This article explains how to query a container (collection, graph, or table) in Azure Cosmos DB. In particular, it covers how in-partition and cross-partition queries work in Azure Cosmos DB.

In-partition query

When you query data from containers, if the query has a partition key filter specified, Azure Cosmos DB automatically optimizes the query. It routes the query to the physical partitions corresponding to the partition key values specified in the filter.

For example, consider the below query with an equality filter on `DeviceId`. If we run this query on a container partitioned on `DeviceId`, this query will filter to a single physical partition.

```
SELECT * FROM c WHERE c.DeviceId = 'XMS-0001'
```

As with the earlier example, this query will also filter to a single partition. Adding the additional filter on `Location` does not change this:

```
SELECT * FROM c WHERE c.DeviceId = 'XMS-0001' AND c.Location = 'Seattle'
```

Here's a query that has a range filter on the partition key and won't be scoped to a single physical partition. In order to be an in-partition query, the query must have an equality filter that includes the partition key:

```
SELECT * FROM c WHERE c.DeviceId > 'XMS-0001'
```

Cross-partition query

The following query doesn't have a filter on the partition key (`DeviceId`). Therefore, it must fan-out to all physical partitions where it is run against each partition's index:

```
SELECT * FROM c WHERE c.Location = 'Seattle`
```

Each physical partition has its own index. Therefore, when you run a cross-partition query on a container, you are effectively running one query *per* physical partition. Azure Cosmos DB will automatically aggregate results across different physical partitions.

The indexes in different physical partitions are independent from one another. There is no global index in Azure Cosmos DB.

Parallel cross-partition query

The Azure Cosmos DB SDKs 1.9.0 and later support parallel query execution options. Parallel cross-partition queries allow you to perform low latency, cross-partition queries.

You can manage parallel query execution by tuning the following parameters:

- **MaxConcurrency**: Sets the maximum number of simultaneous network connections to the container's partitions. If you set this property to `-1`, the SDK manages the degree of parallelism. If the `MaxConcurrency` set to `0`, there is a single network connection to the container's partitions.
- **MaxBufferedItemCount**: Trades query latency versus client-side memory utilization. If this option is omitted or to set to -1, the SDK manages the number of items buffered during parallel query execution.

Because of the Azure Cosmos DB's ability to parallelize cross-partition queries, query latency will generally scale well as the system adds physical partitions. However, RU charge will increase significantly as the total number of physical partitions increases.

When you run a cross-partition query, you are essentially doing a separate query per individual physical partition. While cross-partition queries queries will use the index, if available, they are still not nearly as efficient as in-partition queries.

Useful example

Here's an analogy to better understand cross-partition queries:

Let's imagine you are a delivery driver that has to deliver packages to different apartment complexes. Each apartment complex has a list on the premises that has all of the resident's unit numbers. We can compare each apartment complex to a physical partition and each list to the physical partition's index.

We can compare in-partition and cross-partition queries using this example:

In-partition query

If the delivery driver knows the correct apartment complex (physical partition), then they can immediately drive to the correct building. The driver can check the apartment complex's list of the resident's unit numbers (the index) and quickly deliver the appropriate packages. In this case, the driver does not waste any time or effort driving to an apartment complex to check and see if any package recipients live there.

Cross-partition query (fan-out)

If the delivery driver does not know the correct apartment complex (physical partition), they'll need to drive to every single apartment building and check the list with all of the resident's unit numbers (the index). Once they arrive at each apartment complex, they'll still be able to use the list of the addresses of each resident. However, they will need to check every apartment complex's list, whether any package recipients live there or not. This is how cross-partition queries work. While they can use the index (don't need to knock on every single door), they must separately check the index for every physical partition.

Cross-partition query (scoped to only a few physical partitions)

If the delivery driver knows that all package recipients live within a certain few apartment complexes, they won't need to drive to every single one. While driving to a few apartment complexes will still require more work than visiting just a single building, the delivery driver still saves significant time and effort. If a query has the partition key in its filter with the `IN` keyword, it will only check the relevant physical partition's indexes for data.

Avoiding cross-partition queries

For most containers, it's inevitable that you will have some cross-partition queries. Having some cross-partition queries is ok! Nearly all query operations are supported across partitions (both logical partition keys and physical partitions). Azure Cosmos DB also has many optimizations in the query engine and client SDKs to parallelize query execution across physical partitions.

For most read-heavy scenarios, we recommend simply selecting the most common property in your query filters. You should also make sure your partition key adheres to other partition key selection best practices.

Avoiding cross-partition queries typically only matters with large containers. You are charged a minimum of about 2.5 RU's each time you check a physical partition's index for results, even if no items in the physical partition match the query's filter. As such, if you have only one (or just a few) physical partitions, cross-partition queries will not consume significantly more RU's than in-partition queries.

The number of physical partitions is tied to the amount of provisioned RU's. Each physical partition allows for up to 10,000 provisioned RU's and can store up to 50 GB of data. Azure Cosmos DB will automatically manage physical partitions for you. The number of physical partitions in your container is dependent on your provisioned throughput and consumed storage.

You should try to avoid cross-partition queries if your workload meets the criteria below:

- You plan to have over 30,000 RU's provisioned
- You plan to store over 100 GB of data

Migrate non-partitioned containers to partitioned containers

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB supports creating containers without a partition key. Currently you can create non-partitioned containers by using Azure CLI and Azure Cosmos DB SDKs (.Net, Java, NodeJs) that have a version less than or equal to 2.x. You cannot create non-partitioned containers using the Azure portal. However, such non-partitioned containers aren't elastic and have fixed storage capacity of 20 GB and throughput limit of 10K RU/s.

The non-partitioned containers are legacy and you should migrate your existing non-partitioned containers to partitioned containers to scale storage and throughput. Azure Cosmos DB provides a system defined mechanism to migrate your non-partitioned containers to partitioned containers. This document explains how all the existing non-partitioned containers are auto-migrated into partitioned containers. You can take advantage of the auto-migration feature only if you are using the V3 version of SDKs in all the languages.

> **NOTE**
>
> Currently, you cannot migrate Azure Cosmos DB MongoDB and Gremlin API accounts by using the steps described in this document.

Migrate container using the system defined partition key

To support the migration, Azure Cosmos DB provides a system defined partition key named `/_partitionkey` on all the containers that don't have a partition key. You cannot change the partition key definition after the containers are migrated. For example, the definition of a container that is migrated to a partitioned container will be as follows:

```
{
    "Id": "CollId"
  "partitionKey": {
    "paths": [
      "/_partitionKey"
    ],
    "kind": "Hash"
  },
}
```

After the container is migrated, you can create documents by populating the `_partitionKey` property along with the other properties of the document. The `_partitionKey` property represents the partition key of your documents.

Choosing the right partition key is important to utilize the provisioned throughput optimally. For more information, see how to choose a partition key article.

> **NOTE**
>
> You can take advantage of system defined partition key only if you are using the latest/V3 version of SDKs in all the languages.

The following example shows a sample code to create a document with the system defined partition key and read

that document:

JSON representation of the document

```
DeviceInformationItem = new DeviceInformationItem
{
   "id": "elevator/PugetSound/Building44/Floor1/1",
   "deviceId": "3cf4c52d-cc67-4bb8-b02f-f6185007a808",
   "_partitionKey": "3cf4c52d-cc67-4bb8-b02f-f6185007a808"
}

public class DeviceInformationItem
{
    [JsonProperty(PropertyName = "id")]
    public string Id { get; set; }

    [JsonProperty(PropertyName = "deviceId")]
    public string DeviceId { get; set; }

    [JsonProperty(PropertyName = "_partitionKey", NullValueHandling = NullValueHandling.Ignore)]
    public string PartitionKey {get {return this.DeviceId; set; }
}

CosmosContainer migratedContainer = database.Containers["testContainer"];

DeviceInformationItem deviceItem = new DeviceInformationItem() {
  Id = "1234",
  DeviceId = "3cf4c52d-cc67-4bb8-b02f-f6185007a808"
}

ItemResponse<DeviceInformationItem > response =
  await migratedContainer.CreateItemAsync<DeviceInformationItem>(
    deviceItem.PartitionKey,
    deviceItem
  );

// Read back the document providing the same partition key
ItemResponse<DeviceInformationItem> readResponse =
  await migratedContainer.ReadItemAsync<DeviceInformationItem>(
    partitionKey:deviceItem.PartitionKey,
    id: device.Id
  );
```

For the complete sample, see the .Net samples GitHub repository.

Migrate the documents

While the container definition is enhanced with a partition key property, the documents within the container aren't auto migrated. Which means the system partition key property `/_partitionKey` path is not automatically added to the existing documents. You need to repartition the existing documents by reading the documents that were created without a partition key and rewrite them back with `_partitionKey` property in the documents.

Access documents that don't have a partition key

Applications can access the existing documents that don't have a partition key by using the special system property called "PartitionKey.None", this is the value of the non-migrated documents. You can use this property in all the CRUD and query operations. The following example shows a sample to read a single Document from the NonePartitionKey.

```
CosmosItemResponse<DeviceInformationItem> readResponse =
await migratedContainer.Items.ReadItemAsync<DeviceInformationItem>(
  partitionKey: PartitionKey.None,
  id: device.Id
);
```

For the complete sample on how to repartition the documents, see the .Net samples GitHub repository.

Compatibility with SDKs

Older version of Azure Cosmos DB SDKs such as V2.x.x and V1.x.x don't support the system defined partition key property. So, when you read the container definition from an older SDK, it doesn't contain any partition key definition and these containers will behave exactly as before. Applications that are built with the older version of SDKs continue to work with non-partitioned as is without any changes.

If a migrated container is consumed by the latest/V3 version of SDK and you start populating the system defined partition key within the new documents, you cannot access (read, update, delete, query) such documents from the older SDKs anymore.

Known issues

Querying for the count of items that were inserted without a partition key by using V3 SDK may involve higher throughput consumption

If you query from the V3 SDK for the items that are inserted by using V2 SDK, or the items inserted by using the V3 SDK with `PartitionKey.None` parameter, the count query may consume more RU/s if the `PartitionKey.None` parameter is supplied in the FeedOptions. We recommend that you don't supply the `PartitionKey.None` parameter if no other items are inserted with a partition key.

If new items are inserted with different values for the partition key, querying for such item counts by passing the appropriate key in `FeedOptions` will not have any issues. After inserting new documents with partition key, if you need to query just the document count without the partition key value, that query may again incur higher RU/s similar to the regular partitioned collections.

- Work with Azure Cosmos account

Configure time to live in Azure Cosmos DB

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

In Azure Cosmos DB, you can choose to configure Time to Live (TTL) at the container level, or you can override it at an item level after setting for the container. You can configure TTL for a container by using Azure portal or the language-specific SDKs. Item level TTL overrides can be configured by using the SDKs.

> This content is related to Azure Cosmos DB transactional store TTL. If you are looking for analitycal store TTL, that enables NoETL HTAP scenarios through Azure Synapse Link, please click here.

Enable time to live on a container using Azure portal

Use the following steps to enable time to live on a container with no expiration. Enable this to allow TTL to be overridden at the item level. You can also set the TTL by entering a non-zero value for seconds.

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account or selectan existing account.
3. Open the **Data Explorer** pane.
4. Select an existing container, expand it and modify the following values:
   - Open the **Scale & Settings** window.
   - Under **Setting** find, **Time to Live**.
   - Select **On (no default)** or select **On** and set a TTL value
   - Click **Save** to save the changes.

- When DefaultTimeToLive is null then your Time to Live is Off
- When DefaultTimeToLive is -1 then your Time to Live setting is On (No default)
- When DefaultTimeToLive has any other Int value (except 0) your Time to Live setting is On

Enable time to live on a container using Azure CLI or PowerShell

To create or enable TTL on a container see,

- Create a container with TTL using Azure CLI
- Create a container with TTL using PowerShell

Enable time to live on a container using SDK

.NET SDK

- .NET SDK V2
- .NET SDK V3

.NET SDK V2 (Microsoft.Azure.DocumentDB)

```
// Create a new container with TTL enabled and without any expiration value
DocumentCollection collectionDefinition = new DocumentCollection();
collectionDefinition.Id = "myContainer";
collectionDefinition.PartitionKey.Paths.Add("/myPartitionKey");
collectionDefinition.DefaultTimeToLive = -1; //(never expire by default)

DocumentCollection ttlEnabledCollection = await client.CreateDocumentCollectionAsync(
    UriFactory.CreateDatabaseUri("myDatabaseName"),
    collectionDefinition);
```

Java SDK

- Java SDK V4
- Java SDK V3

Java SDK V4 (Maven com.azure::azure-cosmos)

```
CosmosAsyncContainer container;

// Create a new container with TTL enabled and without any expiration value
CosmosContainerProperties containerProperties = new CosmosContainerProperties("myContainer",
"/myPartitionKey");
containerProperties.setDefaultTimeToLiveInSeconds(-1);
container = database.createContainerIfNotExists(containerProperties, 400).block().getContainer();
```

Set time to live on a container using SDK

To set the time to live on a container, you need to provide a non-zero positive number that indicates the time period in seconds. Based on the configured TTL value, all items in the container after the last modified timestamp of the item `_ts` are deleted. You can optionally set `TimeToLivePropertyPath`, which will use a different property instead of the system-generated `_ts` property to determine which items to delete based on TTL.

.NET SDK

- .NET SDK V2
- .NET SDK V3

.NET SDK V2 (Microsoft.Azure.DocumentDB)

```
// Create a new container with TTL enabled and a 90 day expiration
DocumentCollection collectionDefinition = new DocumentCollection();
collectionDefinition.Id = "myContainer";
collectionDefinition.PartitionKey.Paths.Add("/myPartitionKey");
collectionDefinition.DefaultTimeToLive = 90 * 60 * 60 * 24 // expire all documents after 90 days

DocumentCollection ttlEnabledCollection = await client.CreateDocumentCollectionAsync(
    UriFactory.CreateDatabaseUri("myDatabaseName"),
    collectionDefinition;
```

Java SDK

- Java SDK V4
- Java SDK V3

Java SDK V4 (Maven com.azure::azure-cosmos)

```
CosmosAsyncContainer container;

// Create a new container with TTL enabled with default expiration value
CosmosContainerProperties containerProperties = new CosmosContainerProperties("myContainer",
"/myPartitionKey");
containerProperties.setDefaultTimeToLiveInSeconds(90 * 60 * 60 * 24);
container = database.createContainerIfNotExists(containerProperties, 400).block().getContainer();
```

NodeJS SDK

```
const containerDefinition = {
          id: "sample container1",
        };

async function createcontainerWithTTL(db: Database, containerDefinition: ContainerDefinition, collId: any,
defaultTtl: number) {
      containerDefinition.id = collId;
      containerDefinition.defaultTtl = defaultTtl;
      await db.containers.create(containerDefinition);
}
```

Set time to live on an item

In addition to setting a default time to live on a container, you can set a time to live for an item. Setting time to live at the item level will override the default TTL of the item in that container.

- To set the TTL on an item, you need to provide a non-zero positive number, which indicates the period, in seconds, to expire the item after the last modified timestamp of the item `_ts`.
- If the item doesn't have a TTL field, then by default, the TTL set to the container will apply to the item.
- If TTL is disabled at the container level, the TTL field on the item will be ignored until TTL is re-enabled on the container.

Azure portal

Use the following steps to enable time to live on an item:

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account or selectan existing account.
3. Open the **Data Explorer** pane.
4. Select an existing container, expand it and modify the following values:
   - Open the **Scale & Settings** window.
   - Under **Setting** find, **Time to Live**.
   - Select **On (no default)** or select **On** and set a TTL value.
   - Click **Save** to save the changes.
5. Next navigate to the item for which you want to set time to live, add the `ttl` property and select **Update**.

```
{
 "id": "1",
 "_rid": "Jic9ANWdO-EFAAAAAAAAAA==",
 "_self": "dbs/Jic9AA==/colls/Jic9ANWdO-E=/docs/Jic9ANWdO-EFAAAAAAAAAA==/",
 "_etag": "\"0d00b23f-0000-0000-0000-5c7712e80000\"",
 "_attachments": "attachments/",
 "ttl": 10,
 "_ts": 1551307496
}
```

.NET SDK (any)

```
// Include a property that serializes to "ttl" in JSON
public class SalesOrder
{
    [JsonProperty(PropertyName = "id")]
    public string Id { get; set; }
    [JsonProperty(PropertyName="cid")]
    public string CustomerId { get; set; }
    // used to set expiration policy
    [JsonProperty(PropertyName = "ttl", NullValueHandling = NullValueHandling.Ignore)]
    public int? ttl { get; set; }

    //...
}
// Set the value to the expiration in seconds
SalesOrder salesOrder = new SalesOrder
{
    Id = "SO05",
    CustomerId = "CO18009186470",
    ttl = 60 * 60 * 24 * 30;  // Expire sales orders in 30 days
};
```

NodeJS SDK

```
const itemDefinition = {
          id: "doc",
          name: "sample Item",
          key: "value",
          ttl: 2
        };
```

Java SDK

- Java SDK V4
- Java SDK V3

Java SDK V4 (Maven com.azure::azure-cosmos)

```
// Include a property that serializes to "ttl" in JSON
public class SalesOrder
{
    private String id;
    private String customerId;
    private Integer ttl;

    public SalesOrder(String id, String customerId, Integer ttl) {
        this.id = id;
        this.customerId = customerId;
        this.ttl = ttl;
    }

    public String getId() {return this.id;}
    public void setId(String new_id) {this.id = new_id;}
    public String getCustomerId() {return this.customerId;}
    public void setCustomerId(String new_cid) {this.customerId = new_cid;}
    public Integer getTtl() {return this.ttl;}
    public void setTtl(Integer new_ttl) {this.ttl = new_ttl;}

    //...
}

// Set the value to the expiration in seconds
SalesOrder salesOrder = new SalesOrder(
    "SO05",
    "CO18009186470",
    60 * 60 * 24 * 30  // Expire sales orders in 30 days
);
```

Reset time to live

You can reset the time to live on an item by performing a write or update operation on the item. The write or update operation will set the `_ts` to the current time, and the TTL for the item to expire will begin again. If you wish to change the TTL of an item, you can update the field just as you update any other field.

.NET SDK

- .NET SDK V2
- .NET SDK V3

.NET SDK V2 (Microsoft.Azure.DocumentDB)

```
// This examples leverages the Sales Order class above.
// Read a document, update its TTL, save it.
response = await client.ReadDocumentAsync(
    "/dbs/salesdb/colls/orders/docs/SO05"),
    new RequestOptions { PartitionKey = new PartitionKey("CO18009186470") });

Document readDocument = response.Resource;
readDocument.ttl = 60 * 30 * 30; // update time to live
response = await client.ReplaceDocumentAsync(readDocument);
```

Java SDK

- Java SDK V4
- Java SDK V3

Java SDK V4 (Maven com.azure::azure-cosmos)

```
// This examples leverages the Sales Order class above.
// Read a document, update its TTL, save it.
CosmosAsyncItemResponse<SalesOrder> itemResponse = container.readItem("SO05", new
PartitionKey("CO18009186470"), SalesOrder.class)
        .flatMap(readResponse -> {
            SalesOrder salesOrder = readResponse.getItem();
            salesOrder.setTtl(60 * 30 * 30);
            return container.createItem(salesOrder);
}).block();
```

Turn off time to live

If time to live has been set on an item and you no longer want that item to expire, then you can get the item, remove the TTL field, and replace the item on the server. When the TTL field is removed from the item, the default TTL value assigned to the container is applied to the item. Set the TTL value to -1 to prevent an item from expiring and to not inherit the TTL value from the container.

.NET SDK

- .NET SDK V2
- .NET SDK V3

.NET SDK V2 (Microsoft.Azure.DocumentDB)

```
// This examples leverages the Sales Order class above.
// Read a document, turn off its override TTL, save it.
response = await client.ReadDocumentAsync(
    "/dbs/salesdb/colls/orders/docs/SO05"),
    new RequestOptions { PartitionKey = new PartitionKey("CO18009186470") });

Document readDocument = response.Resource;
readDocument.ttl = null; // inherit the default TTL of the container

response = await client.ReplaceDocumentAsync(readDocument);
```

Java SDK

- Java SDK V4
- Java SDK V3

Java SDK V4 (Maven com.azure::azure-cosmos)

```
// This examples leverages the Sales Order class above.
// Read a document, update its TTL, save it.
CosmosAsyncItemResponse<SalesOrder> itemResponse = container.readItem("SO05", new
PartitionKey("CO18009186470"), SalesOrder.class)
        .flatMap(readResponse -> {
            SalesOrder salesOrder = readResponse.getItem();
            salesOrder.setTtl(null);
            return container.createItem(salesOrder);
}).block();
```

Disable time to live

To disable time to live on a container and stop the background process from checking for expired items, the `DefaultTimeToLive` property on the container should be deleted. Deleting this property is different from setting it to -1. When you set it to -1, new items added to the container will live forever, however you can override this value on specific items in the container. When you remove the TTL property from the container the items will never

expire, even if there are they have explicitly overridden the previous default TTL value.

.NET SDK

- .NET SDK V2
- .NET SDK V3

.NET SDK V2 (Microsoft.Azure.DocumentDB)

```
// Get the container, update DefaultTimeToLive to null
DocumentCollection collection = await client.ReadDocumentCollectionAsync("/dbs/salesdb/colls/orders");
// Disable TTL
collection.DefaultTimeToLive = null;
await client.ReplaceDocumentCollectionAsync(collection);
```

Java SDK

- Java SDK V4
- Java SDK V3

Java SDK V4 (Maven com.azure::azure-cosmos)

```
CosmosContainerProperties containerProperties = new CosmosContainerProperties("myContainer",
"/myPartitionKey");
// Disable TTL
containerProperties.setDefaultTimeToLiveInSeconds(null);
// Update container settings
container.replace(containerProperties).block();
```

- Time to live

Define unique keys for an Azure Cosmos container

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article presents the different ways to define unique keys when creating an Azure Cosmos container. It's currently possible to perform this operation either by using the Azure portal or through one of the SDKs.

Use the Azure portal

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account or selectan existing one.
3. Open the **Data Explorer** pane and select the container that you want to work on.
4. Click on **New Container**.
5. In the **Add Container** dialog, click on **+ Add unique key** to add a unique key entry.
6. Enter the path(s) of the unique key constraint
7. If needed, add more unique key entries by clicking on **+ Add unique key**

Use PowerShell

To create a container with unique keys see, Create an Azure Cosmos container with unique key and TTL

Use the .NET SDK

- .NET SDK V2
- .NET SDK V3

When creating a new container using the .NET SDK v2, a `UniqueKeyPolicy` object can be used to define unique key constraints.

```
client.CreateDocumentCollectionAsync(UriFactory.CreateDatabaseUri("database"), new DocumentCollection
{
    Id = "container",
    PartitionKey = new PartitionKeyDefinition { Paths = new Collection<string>(new List<string> {
"/myPartitionKey" }) },
    UniqueKeyPolicy = new UniqueKeyPolicy
    {
        UniqueKeys = new Collection<UniqueKey>(new List<UniqueKey>
        {
            new UniqueKey { Paths = new Collection<string>(new List<string> { "/firstName", "/lastName",
"/emailAddress" }) },
            new UniqueKey { Paths = new Collection<string>(new List<string> { "/address/zipCode" }) }
        })
    }
});
```

Use the Java SDK

When creating a new container using the Java SDK, a `UniqueKeyPolicy` object can be used to define unique key constraints.

```
// create a new DocumentCollection object
DocumentCollection container = new DocumentCollection();
container.setId("container");

// create array of strings and populate them with the unique key paths
Collection<String> uniqueKey1Paths = new ArrayList<String>();
uniqueKey1Paths.add("/firstName");
uniqueKey1Paths.add("/lastName");
uniqueKey1Paths.add("/emailAddress");
Collection<String> uniqueKey2Paths = new ArrayList<String>();
uniqueKey2Paths.add("/address/zipCode");

// create UniqueKey objects and set their paths
UniqueKey uniqueKey1 = new UniqueKey();
UniqueKey uniqueKey2 = new UniqueKey();
uniqueKey1.setPaths(uniqueKey1Paths);
uniqueKey2.setPaths(uniqueKey2Paths);

// create a new UniqueKeyPolicy object and set its unique keys
UniqueKeyPolicy uniqueKeyPolicy = new UniqueKeyPolicy();
Collection<UniqueKey> uniqueKeys = new ArrayList<UniqueKey>();
uniqueKeys.add(uniqueKey1);
uniqueKeys.add(uniqueKey2);
uniqueKeyPolicy.setUniqueKeys(uniqueKeys);

// set the unique key policy
container.setUniqueKeyPolicy(uniqueKeyPolicy);

// create the container
client.createCollection(String.format("/dbs/%s", "database"), container, null);
```

Use the Node.js SDK

When creating a new container using the Node.js SDK, a `UniqueKeyPolicy` object can be used to define unique key constraints.

```
client.database('database').containers.create({
    id: 'container',
    uniqueKeyPolicy: {
        uniqueKeys: [
            { paths: ['/firstName', '/lastName', '/emailAddress'] },
            { paths: ['/address/zipCode'] }
        ]
    }
});
```

Use the Python SDK

When creating a new container using the Python SDK, unique key constraints can be specified as part of the dictionary passed as parameter.

```
client.CreateContainer('dbs/' + config['DATABASE'], {
    'id': 'container',
    'uniqueKeyPolicy': {
        'uniqueKeys': [
            {'paths': ['/firstName', '/lastName', '/emailAddress']},
            {'paths': ['/address/zipCode']}
        ]
    }
})
```

Transactional batch operations in Azure Cosmos DB using the .NET SDK

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

Transactional batch describes a group of point operations that need to either succeed or fail together with the same partition key in a container. In the .NET SDK, the `TranscationalBatch` class is used to define this batch of operations. If all operations succeed in the order they are described within the transactional batch operation, the transaction will be committed. However, if any operation fails, the entire transaction is rolled back.

What's a transaction in Azure Cosmos DB

A transaction in a typical database can be defined as a sequence of operations performed as a single logical unit of work. Each transaction provides ACID (Atomicity, Consistency, Isolation, Durability) property guarantees.

- **Atomicity** guarantees that all the operations done inside a transaction are treated as a single unit, and either all of them are committed or none of them are.
- **Consistency** makes sure that the data is always in a valid state across transactions.
- **Isolation** guarantees that no two transactions interfere with each other – many commercial systems provide multiple isolation levels that can be used based on the application needs.
- **Durability** ensures that any change that is committed in a database will always be present. Azure Cosmos DB supports full ACID compliant transactions with snapshot isolation for operations within the same logical partition key.

Transactional batch operations Vs stored procedures

Azure Cosmos DB currently supports stored procedures, which also provide the transactional scope on operations. However, transactional batch operations offer the following benefits:

- **Language option** – Transactional batch is supported on the SDK and language you work with already, while stored procedures need to be written in JavaScript.
- **Code versioning** – Versioning application code and onboarding it onto your CI/CD pipeline is much more natural than orchestrating the update of a stored procedure and making sure the rollover happens at the right time. It also makes rolling back changes easier.
- **Performance** – Reduced the latency on equivalent operations up to 30% when compared to the stored procedure execution.
- **Content serialization** – Each operation within a transactional batch can leverage custom serialization options for its payload.

How to create a transactional batch operation

When creating a transactional batch operation, you begin from a container instance and call `CreateTransactionalBatch`:

```
string partitionKey = "The Family";
ParentClass parent = new ParentClass(){ Id = "The Parent", PartitionKey = partitionKey, Name = "John", Age =
30 };
ChildClass child = new ChildClass(){ Id = "The Child", ParentId = parent.Id, PartitionKey = partitionKey };
TransactionalBatch batch = container.CreateTransactionalBatch(new PartitionKey(parent.PartitionKey))
  .CreateItem<ParentClass>(parent)
  .CreateItem<ChildClass>(child);
```

Next, you'll need to call the `ExecuteAsync`:

```
TransactionalBatchResponse batchResponse = await batch.ExecuteAsync();
```

Once the response is received, you'll need to examine if it is successful or not, and extract the results:

```
using (batchResponse)
{
  if (batchResponse.IsSuccessStatusCode)
  {
    TransactionalBatchOperationResult<ParentClass> parentResult =
batchResponse.GetOperationResultAtIndex<ParentClass>(0);
    ParentClass parentClassResult = parentResult.Resource;
    TransactionalBatchOperationResult<ChildClass> childResult =
batchResponse.GetOperationResultAtIndex<ChildClass>(1);
    ChildClass childClassResult = childResult.Resource;
  }
}
```

If there is a failure, the failed operation will have a status code of its corresponding error. Whereas all the other operations will have a 424 status code (failed dependency). In the example below, the operation fails because it tries to create an item that already exists (409 HttpStatusCode.Conflict). Status codes make it easier to identify the cause of transaction failure.

```
// Parent's birthday!
parent.Age = 31;
// Naming two children with the same name, should abort the transaction
ChildClass anotherChild = new ChildClass(){ Id = "The Child", ParentId = parent.Id, PartitionKey =
partitionKey };
TransactionalBatchResponse failedBatchResponse = await container.CreateTransactionalBatch(new
PartitionKey(partitionKey))
  .ReplaceItem<ParentClass>(parent.Id, parent)
  .CreateItem<ChildClass>(anotherChild)
  .ExecuteAsync();

using (failedBatchResponse)
{
  if (!failedBatchResponse.IsSuccessStatusCode)
  {
    TransactionalBatchOperationResult<ParentClass> parentResult =
failedBatchResponse.GetOperationResultAtIndex<ParentClass>(0);
    // parentResult.StatusCode is 424
    TransactionalBatchOperationResult<ChildClass> childResult =
failedBatchResponse.GetOperationResultAtIndex<ChildClass>(1);
    // childResult.StatusCode is 409
  }
}
```

How are transactional batch operations executed

When the `ExecuteAsync` method is called, all operations in the `TransactionalBatch` object are grouped, serialized

into a single payload, and sent as a single request to the Azure Cosmos DB service.

The service receives the request and executes all operations within a transactional scope, and returns a response using the same serialization protocol. This response is either a success, or a failure, and contains all the individual operation responses internally.

The SDK exposes the response for you to verify the result and, optionally, extract each of the internal operation results.

Limitations

Currently, there are two known limits:

- Azure Cosmos DB request size limit specifies the size of the `TransactionalBatch` payload cannot exceed 2 MB, and the maximum execution time is 5 seconds.
- There is a current limit of 100 operations per `TransactionalBatch` to make sure the performance is as expected and within SLAs.

Get SQL query execution metrics and analyze query performance using .NET SDK

11/2/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This article presents how to profile SQL query performance on Azure Cosmos DB. This profiling can be done using `QueryMetrics` retrieved from the .NET SDK and is detailed here. QueryMetrics is a strongly typed object with information about the backend query execution. These metrics are documented in more detail in the Tune Query Performance article.

Set the FeedOptions parameter

All the overloads for DocumentClient.CreateDocumentQuery take in an optional FeedOptions parameter. This option is what allows query execution to be tuned and parameterized.

To collect the Sql query execution metrics, you must set the parameter PopulateQueryMetrics in the FeedOptions to `true`. Setting `PopulateQueryMetrics` to true will make it so that the `FeedResponse` will contain the relevant `QueryMetrics`.

Get query metrics with AsDocumentQuery()

The following code sample shows how to do retrieve metrics when using AsDocumentQuery() method:

```
// Initialize this DocumentClient and Collection
DocumentClient documentClient = null;
DocumentCollection collection = null;

// Setting PopulateQueryMetrics to true in the FeedOptions
FeedOptions feedOptions = new FeedOptions
{
    PopulateQueryMetrics = true
};

string query = "SELECT TOP 5 * FROM c";
IDocumentQuery<dynamic> documentQuery = documentClient.CreateDocumentQuery(Collection.SelfLink, query,
feedOptions).AsDocumentQuery();

while (documentQuery.HasMoreResults)
{
    // Execute one continuation of the query
    FeedResponse<dynamic> feedResponse = await documentQuery.ExecuteNextAsync();

    // This dictionary maps the partitionId to the QueryMetrics of that query
    IReadOnlyDictionary<string, QueryMetrics> partitionIdToQueryMetrics = feedResponse.QueryMetrics;

    // At this point you have QueryMetrics which you can serialize using .ToString()
    foreach (KeyValuePair<string, QueryMetrics> kvp in partitionIdToQueryMetrics)
    {
        string partitionId = kvp.Key;
        QueryMetrics queryMetrics = kvp.Value;

        // Do whatever logging you need
        DoSomeLoggingOfQueryMetrics(query, partitionId, queryMetrics);
    }
}
```

Aggregating QueryMetrics

In the previous section, notice that there were multiple calls to ExecuteNextAsync method. Each call returned a `FeedResponse` object that has a dictionary of `QueryMetrics`; one for every continuation of the query. The following example shows how to aggregate these `QueryMetrics` using LINQ:

```
List<QueryMetrics> queryMetricsList = new List<QueryMetrics>();

while (documentQuery.HasMoreResults)
{
    // Execute one continuation of the query
    FeedResponse<dynamic> feedResponse = await documentQuery.ExecuteNextAsync();

    // This dictionary maps the partitionId to the QueryMetrics of that query
    IReadOnlyDictionary<string, QueryMetrics> partitionIdToQueryMetrics = feedResponse.QueryMetrics;
    queryMetricsList.AddRange(partitionIdToQueryMetrics.Values);
}

// Aggregate the QueryMetrics using the + operator overload of the QueryMetrics class.
QueryMetrics aggregatedQueryMetrics = queryMetricsList.Aggregate((curr, acc) => curr + acc);
Console.WriteLine(aggregatedQueryMetrics);
```

Grouping query metrics by Partition ID

You can group the `QueryMetrics` by the Partition ID. Grouping by Partition ID allows you to see if a specific Partition is causing performance issues when compared to others. The following example shows how to group `QueryMetrics` with LINQ:

```
List<KeyValuePair<string, QueryMetrics>> partitionedQueryMetrics = new List<KeyValuePair<string,
QueryMetrics>>();
while (documentQuery.HasMoreResults)
{
    // Execute one continuation of the query
    FeedResponse<dynamic> feedResponse = await documentQuery.ExecuteNextAsync();

    // This dictionary is maps the partitionId to the QueryMetrics of that query
    IReadOnlyDictionary<string, QueryMetrics> partitionIdToQueryMetrics = feedResponse.QueryMetrics;
    partitionedQueryMetrics.AddRange(partitionIdToQueryMetrics.ToList());
}

// Now we are able to group the query metrics by partitionId
IEnumerable<IGrouping<string, KeyValuePair<string, QueryMetrics>>> groupedByQueryMetrics =
partitionedQueryMetrics
    .GroupBy(kvp => kvp.Key);

// If we wanted to we could even aggregate the groupedby QueryMetrics
foreach(IGrouping<string, KeyValuePair<string, QueryMetrics>> grouping in groupedByQueryMetrics)
{
    string partitionId = grouping.Key;
    QueryMetrics aggregatedQueryMetricsForPartition = grouping
        .Select(kvp => kvp.Value)
        .Aggregate((curr, acc) => curr + acc);
    DoSomeLoggingOfQueryMetrics(query, partitionId, aggregatedQueryMetricsForPartition);
}
```

LINQ on DocumentQuery

You can also get the `FeedResponse` from a LINQ Query using the `AsDocumentQuery()` method:

```
IDocumentQuery<Document> linqQuery = client.CreateDocumentQuery(collection.SelfLink, feedOptions)
    .Take(1)
    .Where(document => document.Id == "42")
    .OrderBy(document => document.Timestamp)
    .AsDocumentQuery();
FeedResponse<Document> feedResponse = await linqQuery.ExecuteNextAsync<Document>();
IReadOnlyDictionary<string, QueryMetrics> queryMetrics = feedResponse.QueryMetrics;
```

Expensive Queries

You can capture the request units consumed by each query to investigate expensive queries or queries that consume high throughput. You can get the request charge by using the RequestCharge property in `FeedResponse`. To learn more about how to get the request charge using the Azure portal and different SDKs, see find the request unit charge article.

```
string query = "SELECT * FROM c";
IDocumentQuery<dynamic> documentQuery = documentClient.CreateDocumentQuery(Collection.SelfLink, query,
feedOptions).AsDocumentQuery();

while (documentQuery.HasMoreResults)
{
    // Execute one continuation of the query
    FeedResponse<dynamic> feedResponse = await documentQuery.ExecuteNextAsync();
    double requestCharge = feedResponse.RequestCharge

    // Log the RequestCharge how ever you want.
    DoSomeLogging(requestCharge);
}
```

Get the query execution time

When calculating the time required to execute a client-side query, make sure that you only include the time to call the `ExecuteNextAsync` method and not other parts of your code base. Just these calls help you in calculating how long the query execution took as shown in the following example:

```
string query = "SELECT * FROM c";
IDocumentQuery<dynamic> documentQuery = documentClient.CreateDocumentQuery(Collection.SelfLink, query,
feedOptions).AsDocumentQuery();
Stopwatch queryExecutionTimeEndToEndTotal = new Stopwatch();
while (documentQuery.HasMoreResults)
{
    // Execute one continuation of the query
    queryExecutionTimeEndToEndTotal.Start();
    FeedResponse<dynamic> feedResponse = await documentQuery.ExecuteNextAsync();
    queryExecutionTimeEndToEndTotal.Stop();
}

// Log the elapsed time
DoSomeLogging(queryExecutionTimeEndToEndTotal.Elapsed);
```

Scan queries (commonly slow and expensive)

A scan query refers to a query that wasn't served by the index, due to which, many documents are loaded before returning the result set.

Below is an example of a scan query:

```
SELECT VALUE c.description
FROM   c
WHERE UPPER(c.description) = "BABYFOOD, DESSERT, FRUIT DESSERT, WITHOUT ASCORBIC ACID, JUNIOR"
```

This query's filter uses the system function UPPER, which isn't served from the index. Executing this query against a large collection produced the following query metrics for the first continuation:

```
QueryMetrics

Retrieved Document Count                 :          60,951
Retrieved Document Size                  :     399,998,938 bytes
Output Document Count                    :               7
Output Document Size                     :             510 bytes
Index Utilization                        :            0.00 %
Total Query Execution Time               :        4,500.34 milliseconds
  Query Preparation Times
    Query Compilation Time               :            0.09 milliseconds
    Logical Plan Build Time              :            0.05 milliseconds
    Physical Plan Build Time             :            0.04 milliseconds
    Query Optimization Time              :            0.01 milliseconds
  Index Lookup Time                      :            0.01 milliseconds
  Document Load Time                     :        4,177.66 milliseconds
  Runtime Execution Times
    Query Engine Times                   :          322.16 milliseconds
    System Function Execution Time       :           85.74 milliseconds
    User-defined Function Execution Time :            0.00 milliseconds
  Document Write Time                    :            0.01 milliseconds
Client Side Metrics
  Retry Count                            :               0
  Request Charge                         :        4,059.95 RUs
```

Note the following values from the query metrics output:

```
Retrieved Document Count                  :          60,951
Retrieved Document Size                   :     399,998,938 bytes
```

This query loaded 60,951 documents, which totaled 399,998,938 bytes. Loading this many bytes results in high cost or request unit charge. It also takes a long time to execute the query, which is clear with the total time spent property:

```
Total Query Execution Time                :        4,500.34 milliseconds
```

Meaning that the query took 4.5 seconds to execute (and this was only one continuation).

To optimize this example query, avoid the use of UPPER in the filter. Instead, when documents are created or updated, the `c.description` values must be inserted in all uppercase characters. The query then becomes:

```
SELECT VALUE c.description
FROM   c
WHERE c.description = "BABYFOOD, DESSERT, FRUIT DESSERT, WITHOUT ASCORBIC ACID, JUNIOR"
```

This query is now able to be served from the index.

To learn more about tuning query performance, see the Tune Query Performance article.

Tuning query performance with Azure Cosmos DB

11/2/2020 • 12 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB provides a SQL API for querying data, without requiring schema or secondary indexes. This article provides the following information for developers:

- High-level details on how Azure Cosmos DB's SQL query execution works
- Details on query request and response headers, and client SDK options
- Tips and best practices for query performance
- Examples of how to utilize SQL execution statistics to debug query performance

About SQL query execution

In Azure Cosmos DB, you store data in containers, which can grow to any storage size or request throughput. Azure Cosmos DB seamlessly scales data across physical partitions under the covers to handle data growth or increase in provisioned throughput. You can issue SQL queries to any container using the REST API or one of the supported SQL SDKs.

A brief overview of partitioning: you define a partition key like "city", which determines how data is split across physical partitions. Data belonging to a single partition key (for example, "city" == "Seattle") is stored within a physical partition, but typically a single physical partition has multiple partition keys. When a partition reaches its storage size, the service seamlessly splits the partition into two new partitions, and divides the partition key evenly across these partitions. Since partitions are transient, the APIs use an abstraction of a "partition key range", which denotes the ranges of partition key hashes.

When you issue a query to Azure Cosmos DB, the SDK performs these logical steps:

- Parse the SQL query to determine the query execution plan.
- If the query includes a filter against the partition key, like `SELECT * FROM c WHERE c.city = "Seattle"`, it is routed to a single partition. If the query does not have a filter on partition key, then it is executed in all partitions, and results are merged client side.
- The query is executed within each partition in series or parallel, based on client configuration. Within each partition, the query might make one or more round trips depending on the query complexity, configured page size, and provisioned throughput of the collection. Each execution returns the number of request units consumed by query execution, and optionally, query execution statistics.
- The SDK performs a summarization of the query results across partitions. For example, if the query involves an ORDER BY across partitions, then results from individual partitions are merge-sorted to return results in globally sorted order. If the query is an aggregation like `COUNT`, the counts from individual partitions are summed to produce the overall count.

The SDKs provide various options for query execution. For example, in .NET these options are available in the `FeedOptions` class. The following table describes these options and how they impact query execution time.

OPTION	DESCRIPTION
`EnableCrossPartitionQuery`	Must be set to true for any query that requires to be executed across more than one partition. This is an explicit flag to enable you to make conscious performance tradeoffs during development time.

OPTION	DESCRIPTION
`EnableScanInQuery`	Must be set to true if you have opted out of indexing, but want to run the query via a scan anyway. Only applicable if indexing for the requested filter path is disabled.
`MaxItemCount`	The maximum number of items to return per round trip to the server. By setting to -1, you can let the server manage the number of items. Or, you can lower this value to retrieve only a small number of items per round trip.
`MaxBufferedItemCount`	This is a client-side option, and used to limit the memory consumption when performing cross-partition ORDER BY. A higher value helps reduce the latency of cross-partition sorting.
`MaxDegreeOfParallelism`	Gets or sets the number of concurrent operations run client side during parallel query execution in the Azure Cosmos database service. A positive property value limits the number of concurrent operations to the set value. If it is set to less than 0, the system automatically decides the number of concurrent operations to run.
`PopulateQueryMetrics`	Enables detailed logging of statistics of time spent in various phases of query execution like compilation time, index loop time, and document load time. You can share output from query statistics with Azure Support to diagnose query performance issues.
`RequestContinuation`	You can resume query execution by passing in the opaque continuation token returned by any query. The continuation token encapsulates all state required for query execution.
`ResponseContinuationTokenLimitInKb`	You can limit the maximum size of the continuation token returned by the server. You might need to set this if your application host has limits on response header size. Setting this may increase the overall duration and RUs consumed for the query.

For example, let's take an example query on partition key requested on a collection with `/city` as the partition key and provisioned with 100,000 RU/s of throughput. You request this query using `CreateDocumentQuery<T>` in .NET like the following:

```
IDocumentQuery<dynamic> query = client.CreateDocumentQuery(
    UriFactory.CreateDocumentCollectionUri(DatabaseName, CollectionName),
    "SELECT * FROM c WHERE c.city = 'Seattle'",
    new FeedOptions
    {
        PopulateQueryMetrics = true,
        MaxItemCount = -1,
        MaxDegreeOfParallelism = -1,
        EnableCrossPartitionQuery = true
    }).AsDocumentQuery();

FeedResponse<dynamic> result = await query.ExecuteNextAsync();
```

The SDK snippet shown above, corresponds to the following REST API request:

{"query":"SELECT * FROM c WHERE c.city = 'Seattle'"}
```

Each query execution page corresponds to a REST API `POST` with the `Accept: application/query+json` header, and the SQL query in the body. Each query makes one or more round trips to the server with the `x-ms-continuation` token echoed between the client and server to resume execution. The configuration options in FeedOptions are passed to the server in the form of request headers. For example, `MaxItemCount` corresponds to `x-ms-max-item-count`.

The request returns the following (truncated for readability) response:

```
HTTP/1.1 200 Ok
Cache-Control: no-store, no-cache
Pragma: no-cache
Transfer-Encoding: chunked
Content-Type: application/json
Server: Microsoft-HTTPAPI/2.0
Strict-Transport-Security: max-age=31536000
x-ms-last-state-change-utc: Tue, 27 Jun 2017 21:01:57.561 GMT
x-ms-resource-quota: documentSize=10240;documentsSize=10485760;documentsCount=-1;collectionSize=10485760;
x-ms-resource-usage: documentSize=1;documentsSize=884;documentsCount=2000;collectionSize=1408;
x-ms-item-count: 2000

```

The key response headers returned from the query include the following:

OPTION	DESCRIPTION
`x-ms-item-count`	The number of items returned in the response. This is dependent on the supplied `x-ms-max-item-count`, the number of items that can be fit within the maximum response payload size, the provisioned throughput, and query execution time.
`x-ms-continuation:`	The continuation token to resume execution of the query, if additional results are available.
`x-ms-documentdb-query-metrics`	The query statistics for the execution. This is a delimited string containing statistics of time spent in the various phases of query execution. Returned if `x-ms-documentdb-populatequerymetrics` is set to `True`.
`x-ms-request-charge`	The number of request units consumed by the query.

For details on the REST API request headers and options, see Querying resources using the REST API.

Best practices for query performance

The following are the most common factors that impact Azure Cosmos DB query performance. We dig deeper into each of these topics in this article.

FACTOR	TIP
Provisioned throughput	Measure RU per query, and ensure that you have the required provisioned throughput for your queries.
Partitioning and partition keys	Favor queries with the partition key value in the filter clause for low latency.
SDK and query options	Follow SDK best practices like direct connectivity, and tune client-side query execution options.
Network latency	Account for network overhead in measurement, and use multi-homing APIs to read from the nearest region.
Indexing Policy	Ensure that you have the required indexing paths/policy for the query.
Query execution metrics	Analyze the query execution metrics to identify potential rewrites of query and data shapes.

Provisioned throughput

In Cosmos DB, you create containers of data, each with reserved throughput expressed in request units (RU) per-second. A read of a 1-KB document is 1 RU, and every operation (including queries) is normalized to a fixed number of RUs based on its complexity. For example, if you have 1000 RU/s provisioned for your container, and you have a query like `SELECT * FROM c WHERE c.city = 'Seattle'` that consumes 5 RUs, then you can perform (1000 RU/s) / (5 RU/query) = 200 query/s such queries per second.

If you submit more than 200 queries/sec, the service starts rate-limiting incoming requests above 200/s. The SDKs automatically handle this case by performing a backoff/retry, therefore you might notice a higher latency for these queries. Increasing the provisioned throughput to the required value improves your query latency and

throughput.

To learn more about request units, see Request units.

Partitioning and partition keys

With Azure Cosmos DB, typically queries perform in the following order from fastest/most efficient to slower/less efficient.

- GET on a single partition key and item key
- Query with a filter clause on a single partition key
- Query without an equality or range filter clause on any property
- Query without filters

Queries that need to consult all partitions need higher latency, and can consume higher RUs. Since each partition has automatic indexing against all properties, the query can be served efficiently from the index in this case. You can make queries that span partitions faster by using the parallelism options.

To learn more about partitioning and partition keys, see Partitioning in Azure Cosmos DB.

SDK and query options

See Performance Tips and Performance testing for how to get the best client-side performance from Azure Cosmos DB. This includes using the latest SDKs, configuring platform-specific configurations like default number of connections, frequency of garbage collection, and using lightweight connectivity options like Direct/TCP.

Max Item Count

For queries, the value of `MaxItemCount` can have a significant impact on end-to-end query time. Each round trip to the server will return no more than the number of items in `MaxItemCount` (Default of 100 items). Setting this to a higher value (-1 is maximum, and recommended) will improve your query duration overall by limiting the number of round trips between server and client, especially for queries with large result sets.

```
IDocumentQuery<dynamic> query = client.CreateDocumentQuery(
    UriFactory.CreateDocumentCollectionUri(DatabaseName, CollectionName),
    "SELECT * FROM c WHERE c.city = 'Seattle'",
    new FeedOptions
    {
        MaxItemCount = -1,
    }).AsDocumentQuery();
```

Max Degree of Parallelism

For queries, tune the `MaxDegreeOfParallelism` to identify the best configurations for your application, especially if you perform cross-partition queries (without a filter on the partition-key value). `MaxDegreeOfParallelism` controls the maximum number of parallel tasks, i.e., the maximum of partitions to be visited in parallel.

```
IDocumentQuery<dynamic> query = client.CreateDocumentQuery(
    UriFactory.CreateDocumentCollectionUri(DatabaseName, CollectionName),
    "SELECT * FROM c WHERE c.city = 'Seattle'",
    new FeedOptions
    {
        MaxDegreeOfParallelism = -1,
        EnableCrossPartitionQuery = true
    }).AsDocumentQuery();
```

Let's assume that

- D = Default Maximum number of parallel tasks (= total number of processor in the client machine)
- P = User-specified maximum number of parallel tasks
- N = Number of partitions that needs to be visited for answering a query

Following are implications of how the parallel queries would behave for different values of P.

- (P == 0) => Serial Mode
- (P == 1) => Maximum of one task
- (P > 1) => Min (P, N) parallel tasks
- (P < 1) => Min (N, D) parallel tasks

For SDK release notes, and details on implemented classes and methods see SQL SDKs

Network latency

See Azure Cosmos DB global distribution for how to set up global distribution, and connect to the closest region. Network latency has a significant impact on query performance when you need to make multiple round-trips or retrieve a large result set from the query.

The section on query execution metrics explains how to retrieve the server execution time of queries (`totalExecutionTimeInMs`), so that you can differentiate between time spent in query execution and time spent in network transit.

Indexing policy

See Configuring indexing policy for indexing paths, kinds, and modes, and how they impact query execution. By default, the indexing policy uses Hash indexing for strings, which is effective for equality queries, but not for range queries/order by queries. If you need range queries for strings, we recommend specifying the Range index type for all strings.

By default, Azure Cosmos DB will apply automatic indexing to all data. For high performance insert scenarios, consider excluding paths as this will reduce the RU cost for each insert operation.

Query execution metrics

You can obtain detailed metrics on query execution by passing in the optional `x-ms-documentdb-populatequerymetrics` header (`FeedOptions.PopulateQueryMetrics` in the .NET SDK). The value returned in `x-ms-documentdb-query-metrics` has the following key-value pairs meant for advanced troubleshooting of query execution.

```
IDocumentQuery<dynamic> query = client.CreateDocumentQuery(
    UriFactory.CreateDocumentCollectionUri(DatabaseName, CollectionName),
    "SELECT * FROM c WHERE c.city = 'Seattle'",
    new FeedOptions
    {
        PopulateQueryMetrics = true,
    }).AsDocumentQuery();

FeedResponse<dynamic> result = await query.ExecuteNextAsync();

// Returns metrics by partition key range Id
IReadOnlyDictionary<string, QueryMetrics> metrics = result.QueryMetrics;
```

METRIC	UNIT	DESCRIPTION
`totalExecutionTimeInMs`	milliseconds	Query execution time
`queryCompileTimeInMs`	milliseconds	Query compile time
`queryLogicalPlanBuildTimeInMs`	milliseconds	Time to build logical query plan

METRIC	UNIT	DESCRIPTION
`queryPhysicalPlanBuildTimeInMs`	milliseconds	Time to build physical query plan
`queryOptimizationTimeInMs`	milliseconds	Time spent in optimizing query
`VMExecutionTimeInMs`	milliseconds	Time spent in query runtime
`indexLookupTimeInMs`	milliseconds	Time spent in physical index layer
`documentLoadTimeInMs`	milliseconds	Time spent in loading documents
`systemFunctionExecuteTimeInMs`	milliseconds	Total time spent executing system (built-in) functions in milliseconds
`userFunctionExecuteTimeInMs`	milliseconds	Total time spent executing user-defined functions in milliseconds
`retrievedDocumentCount`	count	Total number of retrieved documents
`retrievedDocumentSize`	bytes	Total size of retrieved documents in bytes
`outputDocumentCount`	count	Number of output documents
`writeOutputTimeInMs`	milliseconds	Query execution time in milliseconds
`indexUtilizationRatio`	ratio (<=1)	Ratio of number of documents matched by the filter to the number of documents loaded

The client SDKs may internally make multiple query operations to serve the query within each partition. The client makes more than one call per-partition if the total results exceed `x-ms-max-item-count`, if the query exceeds the provisioned throughput for the partition, or if the query payload reaches the maximum size per page, or if the query reaches the system allocated timeout limit. Each partial query execution returns a `x-ms-documentdb-query-metrics` for that page.

Here are some sample queries, and how to interpret some of the metrics returned from query execution:

QUERY	SAMPLE METRIC	DESCRIPTION
`SELECT TOP 100 * FROM c`	`"RetrievedDocumentCount": 101`	The number of documents retrieved is 100+1 to match the TOP clause. Query time is mostly spent in `WriteOutputTime` and `DocumentLoadTime` since it is a scan.
`SELECT TOP 500 * FROM c`	`"RetrievedDocumentCount": 501`	RetrievedDocumentCount is now higher (500+1 to match the TOP clause).
`SELECT * FROM c WHERE c.N = 55`	`"IndexLookupTime": "00:00:00.0009500"`	About 0.9 ms is spent in IndexLookupTime for a key lookup, because it's an index lookup on `/N/?`.

QUERY	SAMPLE METRIC	DESCRIPTION
`SELECT * FROM c WHERE c.N > 55`	`"IndexLookupTime": "00:00:00.0017700"`	Slightly more time (1.7 ms) spent in IndexLookupTime over a range scan, because it's an index lookup on `/N/?`.
`SELECT TOP 500 c.N FROM c`	`"IndexLookupTime": "00:00:00.0017700"`	Same time spent on `DocumentLoadTime` as previous queries, but lower `WriteOutputTime` because we're projecting only one property.
`SELECT TOP 500 udf.toPercent(c.N) FROM c`	`"UserDefinedFunctionExecutionTime": "00:00:00.2136500"`	About 213 ms is spent in `UserDefinedFunctionExecutionTime` executing the UDF on each value of `c.N`.
`SELECT TOP 500 c.Name FROM c WHERE STARTSWITH(c.Name, 'Den')`	`"IndexLookupTime": "00:00:00.0006400", "SystemFunctionExecutionTime": "00:00:00.0074100"`	About 0.6 ms is spent in `IndexLookupTime` on `/Name/?`. Most of the query execution time (~7 ms) in `SystemFunctionExecutionTime`.
`SELECT TOP 500 c.Name FROM c WHERE STARTSWITH(LOWER(c.Name), 'den')`	`"IndexLookupTime": "00:00:00", "RetrievedDocumentCount": 2491, "OutputDocumentCount": 500`	Query is performed as a scan because it uses `LOWER`, and 500 out of 2491 retrieved documents are returned.

Indexing policies in Azure Cosmos DB

12/4/2020 • 14 minutes to read • Edit Online

APPLIES TO: SQL API

In Azure Cosmos DB, every container has an indexing policy that dictates how the container's items should be indexed. The default indexing policy for newly created containers indexes every property of every item and enforces range indexes for any string or number. This allows you to get good query performance without having to think about indexing and index management upfront.

In some situations, you may want to override this automatic behavior to better suit your requirements. You can customize a container's indexing policy by setting its *indexing mode*, and include or exclude *property paths*.

> **NOTE**
>
> The method of updating indexing policies described in this article only applies to Azure Cosmos DB's SQL (Core) API. Learn about indexing in Azure Cosmos DB's API for MongoDB

Indexing mode

Azure Cosmos DB supports two indexing modes:

- **Consistent**: The index is updated synchronously as you create, update or delete items. This means that the consistency of your read queries will be the consistency configured for the account.
- **None**: Indexing is disabled on the container. This is commonly used when a container is used as a pure key-value store without the need for secondary indexes. It can also be used to improve the performance of bulk operations. After the bulk operations are complete, the index mode can be set to Consistent and then monitored using the IndexTransformationProgress until complete.

> **NOTE**
>
> Azure Cosmos DB also supports a Lazy indexing mode. Lazy indexing performs updates to the index at a much lower priority level when the engine is not doing any other work. This can result in **inconsistent or incomplete** query results. If you plan to query a Cosmos container, you should not select lazy indexing. New containers cannot select lazy indexing. You can request an exemption by contacting Azure support (except if you are using an Azure Cosmos account in serverless mode which doesn't support lazy indexing).

By default, indexing policy is set to `automatic`. It's achieved by setting the `automatic` property in the indexing policy to `true`. Setting this property to `true` allows Azure CosmosDB to automatically index documents as they are written.

Including and excluding property paths

A custom indexing policy can specify property paths that are explicitly included or excluded from indexing. By optimizing the number of paths that are indexed, you can substantially reduce the latency and RU charge of write operations. These paths are defined following the method described in the indexing overview section with the following additions:

- a path leading to a scalar value (string or number) ends with `/?`

- elements from an array are addressed together through the `/[]` notation (instead of `/0`, `/1` etc.)
- the `/*` wildcard can be used to match any elements below the node

Taking the same example again:

```
{
    "locations": [
        { "country": "Germany", "city": "Berlin" },
        { "country": "France", "city": "Paris" }
    ],
    "headquarters": { "country": "Belgium", "employees": 250 }
    "exports": [
        { "city": "Moscow" },
        { "city": "Athens" }
    ]
}
```

- the `headquarters`'s `employees` path is `/headquarters/employees/?`
- the `locations`' `country` path is `/locations/[]/country/?`
- the path to anything under `headquarters` is `/headquarters/*`

For example, we could include the `/headquarters/employees/?` path. This path would ensure that we index the employees property but would not index additional nested JSON within this property.

Include/exclude strategy

Any indexing policy has to include the root path `/*` as either an included or an excluded path.

- Include the root path to selectively exclude paths that don't need to be indexed. This is the recommended approach as it lets Azure Cosmos DB proactively index any new property that may be added to your model.
- Exclude the root path to selectively include paths that need to be indexed.
- For paths with regular characters that include: alphanumeric characters and _ (underscore), you don't have to escape the path string around double quotes (for example, "/path/?"). For paths with other special characters, you need to escape the path string around double quotes (for example, "/"path-abc"/?"). If you expect special characters in your path, you can escape every path for safety. Functionally, it doesn't make any difference if you escape every path Vs just the ones that have special characters.
- The system property `_etag` is excluded from indexing by default, unless the etag is added to the included path for indexing.
- If the indexing mode is set to **consistent**, the system properties `id` and `_ts` are automatically indexed.

When including and excluding paths, you may encounter the following attributes:

- `kind` can be either `range` or `hash`. Hash index support is limited to equality filters. Range index functionality provides all of the functionality of hash indexes as well as efficient sorting, range filters, system functions. We always recommend using a range index.
- `precision` is a number defined at the index level for included paths. A value of `-1` indicates maximum precision. We recommend always setting this value to `-1`.
- `dataType` can be either `String` or `Number`. This indicates the types of JSON properties which will be

indexed.

When not specified, these properties will have the following default values:

PROPERTY NAME	DEFAULT VALUE
`kind`	`range`
`precision`	`-1`
`dataType`	`String` and `Number`

See this section for indexing policy examples for including and excluding paths.

Include/exclude precedence

If your included paths and excluded paths have a conflict, the more precise path takes precedence.

Here's an example:

Included Path: `/food/ingredients/nutrition/*`

Excluded Path: `/food/ingredients/*`

In this case, the included path takes precedence over the excluded path because it is more precise. Based on these paths, any data in the `food/ingredients` path or nested within would be excluded from the index. The exception would be data within the included path: `/food/ingredients/nutrition/*`, which would be indexed.

Here are some rules for included and excluded paths precedence in Azure Cosmos DB:

- Deeper paths are more precise than narrower paths. for example: `/a/b/?` is more precise than `/a/?` .
- The `/?` is more precise than `/*`. For example `/a/?` is more precise than `/a/*` so `/a/?` takes precedence.
- The path `/*` must be either an included path or excluded path.

Spatial indexes

When you define a spatial path in the indexing policy, you should define which index `type` should be applied to that path. Possible types for spatial indexes include:

- Point
- Polygon
- MultiPolygon
- LineString

Azure Cosmos DB, by default, will not create any spatial indexes. If you would like to use spatial SQL built-in functions, you should create a spatial index on the required properties. See this section for indexing policy examples for adding spatial indexes.

Composite indexes

Queries that have an `ORDER BY` clause with two or more properties require a composite index. You can also

define a composite index to improve the performance of many equality and range queries. By default, no composite indexes are defined so you should add composite indexes as needed.

Unlike with included or excluded paths, you can't create a path with the `/*` wildcard. Every composite path has an implicit `/?` at the end of the path that you don't need to specify. Composite paths lead to a scalar value and this is the only value that is included in the composite index.

When defining a composite index, you specify:

- Two or more property paths. The sequence in which property paths are defined matters.
- The order (ascending or descending).

> **NOTE**
>
> When you add a composite index, the query will utilize existing range indexes until the new composite index addition is complete. Therefore, when you add a composite index, you may not immediately observe performance improvements. It is possible to track the progress of index transformation by using one of the SDKs.

ORDER BY queries on multiple properties:

The following considerations are used when using composite indexes for queries with an `ORDER BY` clause with two or more properties:

- If the composite index paths do not match the sequence of the properties in the `ORDER BY` clause, then the composite index can't support the query.
- The order of composite index paths (ascending or descending) should also match the `order` in the `ORDER BY` clause.
- The composite index also supports an `ORDER BY` clause with the opposite order on all paths.

Consider the following example where a composite index is defined on properties name, age, and _ts:

COMPOSITE INDEX	SAMPLE `ORDER BY` QUERY	SUPPORTED BY COMPOSITE INDEX?
`(name ASC, age ASC)`	`SELECT * FROM c ORDER BY c.name ASC, c.age asc`	`Yes`
`(name ASC, age ASC)`	`SELECT * FROM c ORDER BY c.age ASC, c.name asc`	`No`
`(name ASC, age ASC)`	`SELECT * FROM c ORDER BY c.name DESC, c.age DESC`	`Yes`
`(name ASC, age ASC)`	`SELECT * FROM c ORDER BY c.name ASC, c.age DESC`	`No`
`(name ASC, age ASC, timestamp ASC)`	`SELECT * FROM c ORDER BY c.name ASC, c.age ASC, timestamp ASC`	`Yes`
`(name ASC, age ASC, timestamp ASC)`	`SELECT * FROM c ORDER BY c.name ASC, c.age ASC`	`No`

You should customize your indexing policy so you can serve all necessary `ORDER BY` queries.

Queries with filters on multiple properties

If a query has filters on two or more properties, it may be helpful to create a composite index for these

properties.

For example, consider the following query which has an equality filter on two properties:

```
SELECT * FROM c WHERE c.name = "John" AND c.age = 18
```

This query will be more efficient, taking less time and consuming fewer RU's, if it is able to leverage a composite index on (name ASC, age ASC).

Queries with range filters can also be optimized with a composite index. However, the query can only have a single range filter. Range filters include `>`, `<`, `<=`, `>=`, and `!=`. The range filter should be defined last in the composite index.

Consider the following query with both equality and range filters:

```
SELECT * FROM c WHERE c.name = "John" AND c.age > 18
```

This query will be more efficient with a composite index on (name ASC, age ASC). However, the query would not utilize a composite index on (age ASC, name ASC) because the equality filters must be defined first in the composite index.

The following considerations are used when creating composite indexes for queries with filters on multiple properties

- The properties in the query's filter should match those in composite index. If a property is in the composite index but is not included in the query as a filter, the query will not utilize the composite index.
- If a query has additional properties in the filter that were not defined in a composite index, then a combination of composite and range indexes will be used to evaluate the query. This will require fewer RU's than exclusively using range indexes.
- If a property has a range filter (`>`, `<`, `<=`, `>=`, or `!=`), then this property should be defined last in the composite index. If a query has more than one range filter, it will not utilize the composite index.
- When creating a composite index to optimize queries with multiple filters, the `ORDER` of the composite index will have no impact on the results. This property is optional.
- If you do not define a composite index for a query with filters on multiple properties, the query will still succeed. However, the RU cost of the query can be reduced with a composite index.
- Queries with both aggregates (for example, COUNT or SUM) and filters also benefit from composite indexes.

Consider the following examples where a composite index is defined on properties name, age, and timestamp:

COMPOSITE INDEX	SAMPLE QUERY	SUPPORTED BY COMPOSITE INDEX?
`(name ASC, age ASC)`	`SELECT * FROM c WHERE c.name = "John" AND c.age = 18`	`Yes`
`(name ASC, age ASC)`	`SELECT * FROM c WHERE c.name = "John" AND c.age > 18`	`Yes`
`(name ASC, age ASC)`	`SELECT COUNT(1) FROM c WHERE c.name = "John" AND c.age > 18`	`Yes`
`(name DESC, age ASC)`	`SELECT * FROM c WHERE c.name = "John" AND c.age > 18`	`Yes`

COMPOSITE INDEX	SAMPLE QUERY	SUPPORTED BY COMPOSITE INDEX?
`(name ASC, age ASC)`	`SELECT * FROM c WHERE c.name != "John" AND c.age > 18`	`No`
`(name ASC, age ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.name = "John" AND c.age = 18 AND c.timestamp > 123049923`	`Yes`
`(name ASC, age ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.name = "John" AND c.age < 18 AND c.timestamp = 123049923`	`No`

Queries with a filter as well as an ORDER BY clause

If a query filters on one or more properties and has different properties in the ORDER BY clause, it may be helpful to add the properties in the filter to the `ORDER BY` clause.

For example, by adding the properties in the filter to the ORDER BY clause, the following query could be rewritten to leverage a composite index:

Query using range index:

```
SELECT * FROM c WHERE c.name = "John" ORDER BY c.timestamp
```

Query using composite index:

```
SELECT * FROM c WHERE c.name = "John" ORDER BY c.name, c.timestamp
```

The same pattern and query optimizations can be generalized for queries with multiple equality filters:

Query using range index:

```
SELECT * FROM c WHERE c.name = "John", c.age = 18 ORDER BY c.timestamp
```

Query using composite index:

```
SELECT * FROM c WHERE c.name = "John", c.age = 18 ORDER BY c.name, c.age, c.timestamp
```

The following considerations are used when creating composite indexes to optimize a query with a filter and `ORDER BY` clause:

- If the query filters on properties, these should be included first in the `ORDER BY` clause.
- If the query filters on multiple properties, the equality filters must be the first properties in the `ORDER BY` clause
- If you do not define a composite index on a query with a filter on one property and a separate `ORDER BY` clause using a different property, the query will still succeed. However, the RU cost of the query can be reduced with a composite index, particularly if the property in the `ORDER BY` clause has a high cardinality.
- All considerations for creating composite indexes for `ORDER BY` queries with multiple properties as well as queries with filters on multiple properties still apply.

COMPOSITE INDEX	SAMPLE `ORDER BY` QUERY	SUPPORTED BY COMPOSITE INDEX?
`(name ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.name = "John" ORDER BY c.name ASC, c.timestamp ASC`	`Yes`
`(name ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.name = "John" AND c.timestamp > 1589840355 ORDER BY c.name ASC, c.timestamp ASC`	`Yes`
`(timestamp ASC, name ASC)`	`SELECT * FROM c WHERE c.timestamp > 1589840355 AND c.name = "John" ORDER BY c.timestamp ASC, c.name ASC`	`No`
`(name ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.name = "John" ORDER BY c.timestamp ASC, c.name ASC`	`No`
`(name ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.name = "John" ORDER BY c.timestamp ASC`	`No`
`(age ASC, name ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.age = 18 and c.name = "John" ORDER BY c.age ASC, c.name ASC,c.timestamp ASC`	`Yes`
`(age ASC, name ASC, timestamp ASC)`	`SELECT * FROM c WHERE c.age = 18 and c.name = "John" ORDER BY c.timestamp ASC`	`No`

Modifying the indexing policy

A container's indexing policy can be updated at any time by using the Azure portal or one of the supported SDKs. An update to the indexing policy triggers a transformation from the old index to the new one, which is performed online and in-place (so no additional storage space is consumed during the operation). The old indexing policy is efficiently transformed to the new policy without affecting the write availability, read availability, or the throughput provisioned on the container. Index transformation is an asynchronous operation, and the time it takes to complete depends on the provisioned throughput, the number of items and their size.

> **IMPORTANT**
>
> Index transformation is an operation that consumes Request Units. Request Units consumed by an index transformation aren't currently billed if you are using serverless containers. These Request Units will get billed once serverless becomes generally available.

> **NOTE**
>
> It is possible to track the progress of index transformation by using one of the SDKs.

There is no impact to write availability during any index transformations. The index transformation uses your provisioned RUs but at a lower priority than your CRUD operations or queries.

There is no impact to read availability when adding a new index. Queries will only utilize new indexes once the index transformation is complete. During the index transformation, the query engine will continue to

use existing indexes, so you'll observe similar read performance during the indexing transformation to what you had observed before initiating the indexing change. When adding new indexes, there is also no risk of incomplete or inconsistent query results.

When removing indexes and immediately running queries that filter on the dropped indexes, there is not a guarantee of consistent or complete query results. If you remove multiple indexes and do so in one single indexing policy change, the query engine provides consistent and complete results throughout the index transformation. However, if you remove indexes through multiple indexing policy changes, the query engine will not provide consistent or complete results until all index transformations complete. Most developers do not drop indexes and then immediately try to run queries that utilize these indexes so, in practice, this situation is unlikely.

> **NOTE**
> Where possible, you should always try to group multiple indexing changes into one single indexing policy modification

Indexing policies and TTL

Using the Time-to-Live (TTL) feature requires indexing. This means that:

- it is not possible to activate TTL on a container where the indexing mode is set to `none`,
- it is not possible to set the indexing mode to None on a container where TTL is activated.

For scenarios where no property path needs to be indexed, but TTL is required, you can use an indexing policy with an indexing mode set to `consistent`, no included paths, and `/*` as the only excluded path.

- Indexing overview
- How to manage indexing policy

Manage indexing policies in Azure Cosmos DB

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

In Azure Cosmos DB, data is indexed following indexing policies that are defined for each container. The default indexing policy for newly created containers enforces range indexes for any string or number. This policy can be overridden with your own custom indexing policy.

> **NOTE**
> The method of updating indexing policies described in this article only applies to Azure Cosmos DB's SQL (Core) API. Learn about indexing in Azure Cosmos DB's API for MongoDB and Secondary indexing in Azure Cosmos DB Cassandra API.

Indexing policy examples

Here are some examples of indexing policies shown in their JSON format, which is how they are exposed on the Azure portal. The same parameters can be set through the Azure CLI or any SDK.

Opt-out policy to selectively exclude some property paths

```
{
    "indexingMode": "consistent",
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "excludedPaths": [
        {
            "path": "/path/to/single/excluded/property/?"
        },
        {
            "path": "/path/to/root/of/multiple/excluded/properties/*"
        }
    ]
}
```

This indexing policy is equivalent to the one below which manually sets `kind`, `dataType`, and `precision` to their default values. These properties are no longer necessary to explicitly set and you should omit them from your indexing policy entirely (as shown in above example).

```
{
    "indexingMode": "consistent",
    "includedPaths": [
        {
            "path": "/*",
            "indexes": [
                {
                    "kind": "Range",
                    "dataType": "Number",
                    "precision": -1
                },
                {
                    "kind": "Range",
                    "dataType": "String",
                    "precision": -1
                }
            ]
        }
    ],
    "excludedPaths": [
        {
            "path": "/path/to/single/excluded/property/?"
        },
        {
            "path": "/path/to/root/of/multiple/excluded/properties/*"
        }
    ]
}
```

Opt-in policy to selectively include some property paths

```
{
    "indexingMode": "consistent",
    "includedPaths": [
        {
            "path": "/path/to/included/property/?"
        },
        {
            "path": "/path/to/root/of/multiple/included/properties/*"
        }
    ],
    "excludedPaths": [
        {
            "path": "/*"
        }
    ]
}
```

This indexing policy is equivalent to the one below which manually sets `kind`, `dataType`, and `precision` to their default values. These properties are no longer necessary to explicitly set and you should omit them from your indexing policy entirely (as shown in above example).

```
{
    "indexingMode": "consistent",
    "includedPaths": [
        {
            "path": "/path/to/included/property/?",
            "indexes": [
                {
                    "kind": "Range",
                    "dataType": "Number"
                },
                {
                    "kind": "Range",
                    "dataType": "String"
                }
            ]
        },
        {
            "path": "/path/to/root/of/multiple/included/properties/*",
            "indexes": [
                {
                    "kind": "Range",
                    "dataType": "Number"
                },
                {
                    "kind": "Range",
                    "dataType": "String"
                }
            ]
        }
    ],
    "excludedPaths": [
        {
            "path": "/*"
        }
    ]
}
```

NOTE

It is generally recommended to use an **opt-out** indexing policy to let Azure Cosmos DB proactively index any new property that may be added to your data model.

Using a spatial index on a specific property path only

```
{
    "indexingMode": "consistent",
    "automatic": true,
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "excludedPaths": [
        {
            "path": "/_etag/?"
        }
    ],
    "spatialIndexes": [
        {
            "path": "/path/to/geojson/property/?",
            "types": [
                "Point",
                "Polygon",
                "MultiPolygon",
                "LineString"
            ]
        }
    ]
}
```

Composite indexing policy examples

In addition to including or excluding paths for individual properties, you can also specify a composite index. If you would like to perform a query that has an `ORDER BY` clause for multiple properties, a composite index on those properties is required. Additionally, composite indexes will have a performance benefit for queries that have a multiple filters or both a filter and an ORDER BY clause.

> **NOTE**
>
> Composite paths have an implicit `/?` since only the scalar value at that path is indexed. The `/*` wildcard is not supported in composite paths. You shouldn't specify `/?` or `/*` in a composite path.

Composite index defined for (name asc, age desc):

```
    {
        "automatic":true,
        "indexingMode":"Consistent",
        "includedPaths":[
            {
                "path":"/*"
            }
        ],
        "excludedPaths":[],
        "compositeIndexes":[
            [
                {
                    "path":"/name",
                    "order":"ascending"
                },
                {
                    "path":"/age",
                    "order":"descending"
                }
            ]
        ]
    }
```

The above composite index on name and age is required for Query #1 and Query #2:

Query #1:

```
    SELECT *
    FROM c
    ORDER BY c.name ASC, c.age DESC
```

Query #2:

```
    SELECT *
    FROM c
    ORDER BY c.name DESC, c.age ASC
```

This composite index will benefit Query #3 and Query #4 and optimize the filters:

Query #3:

```
SELECT *
FROM c
WHERE c.name = "Tim"
ORDER BY c.name DESC, c.age ASC
```

Query #4:

```
SELECT *
FROM c
WHERE c.name = "Tim" AND c.age > 18
```

Composite index defined for (name ASC, age ASC) and (name ASC, age DESC):

You can define multiple different composite indexes within the same indexing policy.

```
    {
        "automatic":true,
        "indexingMode":"Consistent",
        "includedPaths":[
            {
                "path":"/*"
            }
        ],
        "excludedPaths":[],
        "compositeIndexes":[
            [
                {
                    "path":"/name",
                    "order":"ascending"
                },
                {
                    "path":"/age",
                    "order":"ascending"
                }
            ],
            [
                {
                    "path":"/name",
                    "order":"ascending"
                },
                {
                    "path":"/age",
                    "order":"descending"
                }
            ]
        ]
    }
```

Composite index defined for (name ASC, age ASC):

It is optional to specify the order. If not specified, the order is ascending.

```
{
        "automatic":true,
        "indexingMode":"Consistent",
        "includedPaths":[
            {
                "path":"/*"
            }
        ],
        "excludedPaths":[],
        "compositeIndexes":[
            [
                {
                    "path":"/name",
                },
                {
                    "path":"/age",
                }
            ]
        ]
}
```

Excluding all property paths but keeping indexing active

This policy can be used in situations where the Time-to-Live (TTL) feature is active but no additional indexes are necessary (to use Azure Cosmos DB as a pure key-value store).

```
{
    "indexingMode": "consistent",
    "includedPaths": [],
    "excludedPaths": [{
        "path": "/*"
    }]
}
```

No indexing

This policy will turn off indexing. If `indexingMode` is set to `none`, you cannot set a TTL on the container.

```
{
    "indexingMode": "none"
}
```

Updating indexing policy

In Azure Cosmos DB, the indexing policy can be updated using any of the below methods:

- from the Azure portal
- using the Azure CLI
- using PowerShell
- using one of the SDKs

An indexing policy update triggers an index transformation. The progress of this transformation can also be tracked from the SDKs.

> **NOTE**
> When updating indexing policy, writes to Azure Cosmos DB will be uninterrupted. Learn more about indexing transformations

Use the Azure portal

Azure Cosmos containers store their indexing policy as a JSON document that the Azure portal lets you directly edit.

1. Sign in to the Azure portal.
2. Create a new Azure Cosmos account or selectan existing account.
3. Open the **Data Explorer** pane and select the container that you want to work on.
4. Click on **Scale & Settings**.
5. Modify the indexing policy JSON document (see examples below)
6. Click **Save** when you are done.

Use the Azure CLI

To create a container with a custom indexing policy see, Create a container with a custom index policy using CLI

Use PowerShell

To create a container with a custom indexing policy see, Create a container with a custom index policy using PowerShell

Use the .NET SDK

- .NET SDK V2
- .NET SDK V3

The `DocumentCollection` object from the .NET SDK v2 exposes an `IndexingPolicy` property that lets you change the `IndexingMode` and add or remove `IncludedPaths` and `ExcludedPaths`.

```
// Retrieve the container's details
ResourceResponse<DocumentCollection> containerResponse = await
client.ReadDocumentCollectionAsync(UriFactory.CreateDocumentCollectionUri("database", "container"));
// Set the indexing mode to consistent
containerResponse.Resource.IndexingPolicy.IndexingMode = IndexingMode.Consistent;
// Add an included path
containerResponse.Resource.IndexingPolicy.IncludedPaths.Add(new IncludedPath { Path = "/*" });
// Add an excluded path
containerResponse.Resource.IndexingPolicy.ExcludedPaths.Add(new ExcludedPath { Path = "/name/*" });
// Add a spatial index
containerResponse.Resource.IndexingPolicy.SpatialIndexes.Add(new SpatialSpec() { Path = "/locations/*",
SpatialTypes = new Collection<SpatialType>() { SpatialType.Point } } );
// Add a composite index
containerResponse.Resource.IndexingPolicy.CompositeIndexes.Add(new Collection<CompositePath> {new
CompositePath() { Path = "/name", Order = CompositePathSortOrder.Ascending }, new CompositePath() { Path =
"/age", Order = CompositePathSortOrder.Descending }});
// Update container with changes
await client.ReplaceDocumentCollectionAsync(containerResponse.Resource);
```

To track the index transformation progress, pass a `RequestOptions` object that sets the `PopulateQuotaInfo` property to `true`.

```
// retrieve the container's details
ResourceResponse<DocumentCollection> container = await
client.ReadDocumentCollectionAsync(UriFactory.CreateDocumentCollectionUri("database", "container"), new
RequestOptions { PopulateQuotaInfo = true });
// retrieve the index transformation progress from the result
long indexTransformationProgress = container.IndexTransformationProgress;
```

Use the Java SDK

The `DocumentCollection` object from the Java SDK (see this Quickstart regarding its usage) exposes `getIndexingPolicy()` and `setIndexingPolicy()` methods. The `IndexingPolicy` object they manipulate lets you change the indexing mode and add or remove included and excluded paths.

```
// Retrieve the container's details
Observable<ResourceResponse<DocumentCollection>> containerResponse =
client.readCollection(String.format("/dbs/%s/colls/%s", "database", "container"), null);
containerResponse.subscribe(result -> {
DocumentCollection container = result.getResource();
IndexingPolicy indexingPolicy = container.getIndexingPolicy();

// Set the indexing mode to consistent
indexingPolicy.setIndexingMode(IndexingMode.Consistent);

// Add an included path

Collection<IncludedPath> includedPaths = new ArrayList<>();
IncludedPath includedPath = new IncludedPath();
includedPath.setPath("/*");
includedPaths.add(includedPath);
indexingPolicy.setIncludedPaths(includedPaths);

// Add an excluded path

Collection<ExcludedPath> excludedPaths = new ArrayList<>();
ExcludedPath excludedPath = new ExcludedPath();
excludedPath.setPath("/name/*");
excludedPaths.add(excludedPath);
indexingPolicy.setExcludedPaths(excludedPaths);

// Add a spatial index

Collection<SpatialSpec> spatialIndexes = new ArrayList<SpatialSpec>();
Collection<SpatialType> collectionOfSpatialTypes = new ArrayList<SpatialType>();

SpatialSpec spec = new SpatialSpec();
spec.setPath("/locations/*");
collectionOfSpatialTypes.add(SpatialType.Point);
spec.setSpatialTypes(collectionOfSpatialTypes);
spatialIndexes.add(spec);

indexingPolicy.setSpatialIndexes(spatialIndexes);

// Add a composite index

Collection<ArrayList<CompositePath>> compositeIndexes = new ArrayList<>();
ArrayList<CompositePath> compositePaths = new ArrayList<>();

CompositePath nameCompositePath = new CompositePath();
nameCompositePath.setPath("/name");
nameCompositePath.setOrder(CompositePathSortOrder.Ascending);

CompositePath ageCompositePath = new CompositePath();
ageCompositePath.setPath("/age");
ageCompositePath.setOrder(CompositePathSortOrder.Descending);

compositePaths.add(ageCompositePath);
compositePaths.add(nameCompositePath);

compositeIndexes.add(compositePaths);
indexingPolicy.setCompositeIndexes(compositeIndexes);

// Update the container with changes

 client.replaceCollection(container, null);
});
```

To track the index transformation progress on a container, pass a `RequestOptions` object that requests the quota info to be populated, then retrieve the value from the `x-ms-documentdb-collection-index-transformation-progress` response header.

```
// set the RequestOptions object
RequestOptions requestOptions = new RequestOptions();
requestOptions.setPopulateQuotaInfo(true);
// retrieve the container's details
Observable<ResourceResponse<DocumentCollection>> containerResponse =
client.readCollection(String.format("/dbs/%s/colls/%s", "database", "container"), requestOptions);
containerResponse.subscribe(result -> {
    // retrieve the index transformation progress from the response headers
    String indexTransformationProgress = result.getResponseHeaders().get("x-ms-documentdb-collection-index-
transformation-progress");
});
```

Use the Node.js SDK

The `ContainerDefinition` interface from Node.js SDK (see this Quickstart regarding its usage) exposes an `indexingPolicy` property that lets you change the `indexingMode` and add or remove `includedPaths` and `excludedPaths`.

Retrieve the container's details

```
const containerResponse = await client.database('database').container('container').read();
```

Set the indexing mode to consistent

```
containerResponse.body.indexingPolicy.indexingMode = "consistent";
```

Add included path including a spatial index

```
containerResponse.body.indexingPolicy.includedPaths.push({
    includedPaths: [
      {
        path: "/age/*",
        indexes: [
          {
            kind: cosmos.DocumentBase.IndexKind.Range,
            dataType: cosmos.DocumentBase.DataType.String
          },
          {
            kind: cosmos.DocumentBase.IndexKind.Range,
            dataType: cosmos.DocumentBase.DataType.Number
          }
        ]
      },
      {
        path: "/locations/*",
        indexes: [
          {
            kind: cosmos.DocumentBase.IndexKind.Spatial,
            dataType: cosmos.DocumentBase.DataType.Point
          }
        ]
      }
    ]
  });
```

Add excluded path

```
containerResponse.body.indexingPolicy.excludedPaths.push({ path: '/name/*' });
```

Update the container with changes

```
const replaceResponse = await
client.database('database').container('container').replace(containerResponse.body);
```

To track the index transformation progress on a container, pass a `RequestOptions` object that sets the `populateQuotaInfo` property to `true`, then retrieve the value from the `x-ms-documentdb-collection-index-transformation-progress` response header.

```
// retrieve the container's details
const containerResponse = await client.database('database').container('container').read({
    populateQuotaInfo: true
});
// retrieve the index transformation progress from the response headers
const indexTransformationProgress = replaceResponse.headers['x-ms-documentdb-collection-index-transformation-
progress'];
```

Use the Python SDK

- Python SDK V3
- Python SDK V4

When using the Python SDK V3 (see this Quickstart regarding its usage), the container configuration is managed as a dictionary. From this dictionary, it is possible to access the indexing policy and all its attributes.

Retrieve the container's details

```
containerPath = 'dbs/database/colls/collection'
container = client.ReadContainer(containerPath)
```

Set the indexing mode to consistent

```
container['indexingPolicy']['indexingMode'] = 'consistent'
```

Define an indexing policy with an included path and a spatial index

```
container["indexingPolicy"] = {

    "indexingMode":"consistent",
    "spatialIndexes":[
                {"path":"/location/*","types":["Point"]}
            ],
    "includedPaths":[{"path":"/age/*","indexes":[]}],
    "excludedPaths":[{"path":"/*"}]
}
```

Define an indexing policy with an excluded path

```
container["indexingPolicy"] = {
    "indexingMode":"consistent",
    "includedPaths":[{"path":"/*","indexes":[]}],
    "excludedPaths":[{"path":"/name/*"}]
}
```

Add a composite index

```
container['indexingPolicy']['compositeIndexes'] = [
                [
                    {
                        "path": "/name",
                        "order": "ascending"
                    },
                    {
                        "path": "/age",
                        "order": "descending"
                    }
                ]
                ]
```

Update the container with changes

```
response = client.ReplaceContainer(containerPath, container)
```

Performance tips for Azure Cosmos DB and .NET

12/4/2020 • 13 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is a fast, flexible distributed database that scales seamlessly with guaranteed latency and throughput levels. You don't have to make major architecture changes or write complex code to scale your database with Azure Cosmos DB. Scaling up and down is as easy as making a single API call. To learn more, see provision container throughput or provision database throughput.

Because Azure Cosmos DB is accessed via network calls, you can make client-side optimizations to achieve peak performance when you use the SQL .NET SDK.

If you're trying to improve your database performance, consider the options presented in the following sections.

Hosting recommendations

For query-intensive workloads, use Windows 64-bit instead of Linux or Windows 32-bit host processing

We recommend Windows 64-bit host processing for improved performance. The SQL SDK includes a native ServiceInterop.dll to parse and optimize queries locally. ServiceInterop.dll is supported only on the Windows x64 platform.

For Linux and other unsupported platforms where ServiceInterop.dll isn't available, an additional network call is made to the gateway to get the optimized query.

The four application types listed here use 32-bit host processing by default. To change host processing to 64-bit processing for your application type, do the following:

- **For executable applications**: In the **Project Properties** window, on the **Build** pane, set the platform target to **x64**.
- **For VSTest-based test projects**: On the Visual Studio **Test** menu, select **Test** > **Test Settings**, and then set **Default Processor Architecture** to **X64**.
- **For locally deployed ASP.NET web applications**: Select **Tools** > **Options** > **Projects and Solutions** > **Web Projects**, and then select **Use the 64-bit version of IIS Express for web sites and projects**.
- **For ASP.NET web applications deployed on Azure**: In the Azure portal, in **Application settings**, select the **64-bit** platform.

> **NOTE**
>
> By default, new Visual Studio projects are set to **Any CPU**. We recommend that you set your project to **x64** so it doesn't switch to **x86**. A project that's set to **Any CPU** can easily switch to **x86** if an x86-only dependency is added.
> The ServiceInterop.dll file needs to be in the folder that the SDK DLL is being executed from. This should be a concern only if you manually copy DLLs or have custom build or deployment systems.

Turn on server-side garbage collection

Reducing the frequency of garbage collection can help in some cases. In .NET, set gcServer to `true`.

Scale out your client workload

If you're testing at high throughput levels, or at rates that are greater than 50,000 Request Units per second (RU/s), the client application could become a workload bottleneck. This is because the machine might cap out on CPU or network utilization. If you reach this point, you can continue to push the Azure Cosmos DB account further by scaling out your client applications across multiple servers.

> **NOTE**
>
> High CPU usage can cause increased latency and request timeout exceptions.

Networking

Connection policy: Use direct connection mode

.NET V3 SDK default connection mode is direct. You configure the connection mode when you create the `CosmosClient` instance in `CosmosClientOptions`. To learn more about different connectivity options, see the connectivity modes article.

```
string connectionString = "<your-account-connection-string>";
CosmosClient client = new CosmosClient(connectionString,
new CosmosClientOptions
{
    ConnectionMode = ConnectionMode.Gateway // ConnectionMode.Direct is the default
});
```

Ephemeral port exhaustion

If you see a high connection volume or high port usage on your instances, first verify that your client instances are singletons. In other words, the client instances should be unique for the lifetime of the application.

When it's running on the TCP protocol, the client optimizes for latency by using the long-lived connections. This is in contrast with the HTTPS protocol, which terminates the connections after two minutes of inactivity.

In scenarios where you have sparse access, and if you notice a higher connection count when compared to Gateway mode access, you can:

- Configure the CosmosClientOptions.PortReuseMode property to `PrivatePortPool` (effective with framework versions 4.6.1 and later and .NET Core versions 2.0 and later). This property allows the SDK to use a small pool of ephemeral ports for various Azure Cosmos DB destination endpoints.
- Configure the CosmosClientOptions.IdleConnectionTimeout property as greater than or equal to 10 minutes. The recommended values are from 20 minutes to 24 hours.

For performance, collocate clients in the same Azure region

When possible, place any applications that call Azure Cosmos DB in the same region as the Azure Cosmos DB database. Here's an approximate comparison: calls to Azure Cosmos DB within the same region finish within 1 millisecond (ms) to 2 ms, but the latency between the West and East coast of the US is more than 50 ms. This latency can vary from request to request, depending on the route taken by the request as it passes from the client to the Azure datacenter boundary.

You can get the lowest possible latency by ensuring that the calling application is located within the same Azure region as the provisioned Azure Cosmos DB endpoint. For a list of available regions, see Azure regions.

Increase the number of threads/tasks

Because calls to Azure Cosmos DB are made over the network, you might need to vary the degree of concurrency of your requests so that the client application spends minimal time waiting between requests. For example, if you're using the .NET Task Parallel Library, create on the order of hundreds of tasks that read from or write to Azure Cosmos DB.

Enable accelerated networking

To reduce latency and CPU jitter, we recommend that you enable accelerated networking on your client virtual machines. For more information, see Create a Windows virtual machine with accelerated networking or Create a Linux virtual machine with accelerated networking.

SDK usage

Install the most recent SDK

The Azure Cosmos DB SDKs are constantly being improved to provide the best performance. To determine the most recent SDK and review improvements, see Azure Cosmos DB SDK.

Use stream APIs

.NET SDK V3 contains stream APIs that can receive and return data without serializing.

Middle-tier applications that don't consume responses directly from the SDK but relay them to other application tiers can benefit from the stream APIs. For examples of stream handling, see the item management samples.

Use a singleton Azure Cosmos DB client for the lifetime of your application

Each `CosmosClient` instance is thread-safe and performs efficient connection management and address caching when it operates in Direct mode. To allow efficient connection management and better SDK client performance, we recommend that you use a single instance per `AppDomain` for the lifetime of the application.

When you're working on Azure Functions, instances should also follow the existing guidelines and maintain a single instance.

Disable content response on write operations

For workloads that have heavy create payloads, set the `EnableContentResponseOnWrite` request option to `false`. The service will no longer return the created or updated resource to the SDK. Normally, because the application has the object that's being created, it doesn't need the service to return it. The header values are still accessible, like a request charge. Disabling the content response can help improve performance, because the SDK no longer needs to allocate memory or serialize the body of the response. It also reduces the network bandwidth usage to further help performance.

```
ItemRequestOptions requestOptions = new ItemRequestOptions() { EnableContentResponseOnWrite = false };
ItemResponse<Book> itemResponse = await this.container.CreateItemAsync<Book>(book, new
PartitionKey(book.pk), requestOptions);
// Resource will be null
itemResponse.Resource
```

Enable Bulk to optimize for throughput instead of latency

Enable *Bulk* for scenarios where the workload requires a large amount of throughput, and latency is not as important. For more information about how to enable the Bulk feature, and to learn which scenarios it should be used for, see Introduction to Bulk support.

Increase System.Net MaxConnections per host when you use Gateway mode

Azure Cosmos DB requests are made over HTTPS/REST when you use Gateway mode. They're subject to the default connection limit per hostname or IP address. You might need to set `MaxConnections` to a higher value (from 100 through 1,000) so that the client library can use multiple simultaneous connections to Azure Cosmos DB. In .NET SDK 1.8.0 and later, the default value for ServicePointManager.DefaultConnectionLimit is 50. To change the value, you can set `Documents.Client.ConnectionPolicy.MaxConnectionLimit` to a higher value.

Tune parallel queries for partitioned collections

SQL .NET SDK supports parallel queries, which enable you to query a partitioned container in parallel. For more information, see code samples related to working with the SDKs. Parallel queries are designed to provide better query latency and throughput than their serial counterpart.

Parallel queries provide two parameters that you can tune to fit your requirements:

- **MaxConcurrency**: Controls the maximum number of partitions that can be queried in parallel.

  Parallel query works by querying multiple partitions in parallel. But data from an individual partition is fetched serially with respect to the query. Setting `MaxConcurrency` in SDK V3 to the number of partitions has the best chance of achieving the most performant query, provided all other system conditions remain the same. If you don't know the number of partitions, you can set the degree of parallelism to a high number. The system will choose the minimum (number of partitions, user provided input) as the degree of parallelism.

  Parallel queries produce the most benefit if the data is evenly distributed across all partitions with respect to the query. If the partitioned collection is partitioned so that all or most of the data returned by a query is concentrated in a few partitions (one partition is the worst case), those partitions will bottleneck the performance of the query.

- **MaxBufferedItemCount**: Controls the number of pre-fetched results.

  Parallel query is designed to pre-fetch results while the current batch of results is being processed by the client. This pre-fetching helps improve the overall latency of a query. The `MaxBufferedItemCount` parameter limits the number of pre-fetched results. Set `MaxBufferedItemCount` to the expected number of results returned (or a higher number) to allow the query to receive the maximum benefit from pre-fetching.

  Pre-fetching works the same way regardless of the degree of parallelism, and there's a single buffer for the data from all partitions.

Implement backoff at RetryAfter intervals

During performance testing, you should increase load until a small rate of requests are throttled. If requests are throttled, the client application should back off throttling for the server-specified retry interval. Respecting the backoff helps ensure that you'll spend a minimal amount of time waiting between retries.

For more information, see RetryAfter.

There's a mechanism for logging additional diagnostics information and troubleshooting latency issues, as shown in the following sample. You can log the diagnostics string for requests that have a higher read latency. The captured diagnostics string will help you understand how many times you received a *429* error for a given request.

```
ItemResponse<Book> readItemResponse = await this.cosmosContainer.ReadItemAsync<Book>("ItemId", new
PartitionKey("PartitionKeyValue"));
readItemResponse.Diagnostics.ToString();
```

Increase the number of threads/tasks

See Increase the number of threads/tasks in the Networking section of this article.

Indexing policy

Exclude unused paths from indexing for faster writes

The Azure Cosmos DB indexing policy also allows you to specify which document paths to include or exclude from indexing by using indexing paths (IndexingPolicy.IncludedPaths and IndexingPolicy.ExcludedPaths).

Indexing only the paths you need can improve write performance, reduce RU charges on write operations, and reduce index storage for scenarios in which the query patterns are known beforehand. This is because indexing costs correlate directly to the number of unique paths indexed. For example, the following code shows how to exclude an entire section of the documents (a subtree) from indexing by using the "*" wildcard:

```
var containerProperties = new ContainerProperties(id: "excludedPathCollection", partitionKeyPath: "/pk" );
containerProperties.IndexingPolicy.IncludedPaths.Add(new IncludedPath { Path = "/*" });
containerProperties.IndexingPolicy.ExcludedPaths.Add(new ExcludedPath { Path = "/nonIndexedContent/*");
Container container = await this.cosmosDatabase.CreateContainerAsync(containerProperties);
```

For more information, see Azure Cosmos DB indexing policies.

Throughput

Measure and tune for lower RU/s usage

Azure Cosmos DB offers a rich set of database operations. These operations include relational and hierarchical queries with Universal Disk Format (UDF) files, stored procedures, and triggers, all operating on the documents within a database collection.

The costs associated with each of these operations vary depending on the CPU, IO, and memory that are required to complete the operation. Instead of thinking about and managing hardware resources, you can think of a Request Unit as a single measure for the resources that are required to perform various database operations and service an application request.

Throughput is provisioned based on the number of Request Units set for each container. Request Unit consumption is evaluated as a units-per-second rate. Applications that exceed the provisioned Request Unit rate for their container are limited until the rate drops below the provisioned level for the container. If your application requires a higher level of throughput, you can increase your throughput by provisioning additional Request Units.

The complexity of a query affects how many Request Units are consumed for an operation. The number of predicates, the nature of the predicates, the number of UDF files, and the size of the source dataset all influence the cost of query operations.

To measure the overhead of any operation (create, update, or delete), inspect the x-ms-request-charge header (or the equivalent `RequestCharge` property in `ResourceResponse\<T>` or `FeedResponse\<T>` in the .NET SDK) to measure the number of Request Units consumed by the operations:

```
// Measure the performance (Request Units) of writes
ItemResponse<Book> response = await container.CreateItemAsync<Book>(myBook, new
PartitionKey(myBook.PkValue));
Console.WriteLine("Insert of item consumed {0} request units", response.RequestCharge);
// Measure the performance (Request Units) of queries
FeedIterator<Book> queryable = container.GetItemQueryIterator<ToDoActivity>(queryString);
while (queryable.HasMoreResults)
    {
        FeedResponse<Book> queryResponse = await queryable.ExecuteNextAsync<Book>();
        Console.WriteLine("Query batch consumed {0} request units", queryResponse.RequestCharge);
    }
```

The request charge that's returned in this header is a fraction of your provisioned throughput (that is, 2,000 RU/s). For example, if the preceding query returns 1,000 1-KB documents, the cost of the operation is 1,000. So, within one second, the server honors only two such requests before it rate-limits later requests. For more information, see Request Units and the Request Unit calculator.

Handle rate limiting/request rate too large

When a client attempts to exceed the reserved throughput for an account, there's no performance degradation at the server and no use of throughput capacity beyond the reserved level. The server preemptively ends the request with RequestRateTooLarge (HTTP status code 429). It returns an x-ms-retry-after-ms header that indicates the amount of time, in milliseconds, that the user must wait before attempting the request again.

```
    HTTP Status 429,
    Status Line: RequestRateTooLarge
    x-ms-retry-after-ms :100
```

The SDKs all implicitly catch this response, respect the server-specified retry-after header, and retry the request. Unless your account is being accessed concurrently by multiple clients, the next retry will succeed.

If you have more than one client cumulatively operating consistently above the request rate, the default retry count that's currently set to 9 internally by the client might not suffice. In this case, the client throws a CosmosException with status code 429 to the application.

You can change the default retry count by setting the `RetryOptions` on the `CosmosClientOptions` instance. By default, the CosmosException with status code 429 is returned after a cumulative wait time of 30 seconds if the request continues to operate above the request rate. This error is returned even when the current retry count is less than the maximum retry count, whether the current value is the default of 9 or a user-defined value.

The automated retry behavior helps improve resiliency and usability for most applications. But it might not be the best behavior when you're doing performance benchmarks, especially when you're measuring latency. The client-observed latency will spike if the experiment hits the server throttle and causes the client SDK to silently retry. To avoid latency spikes during performance experiments, measure the charge that's returned by each operation, and ensure that requests are operating below the reserved request rate.

For more information, see Request Units.

For higher throughput, design for smaller documents

The request charge (that is, the request-processing cost) of a specified operation correlates directly to the size of the document. Operations on large documents cost more than operations on small documents.

Next steps

For a sample application that's used to evaluate Azure Cosmos DB for high-performance scenarios on a few client machines, see Performance and scale testing with Azure Cosmos DB.

To learn more about designing your application for scale and high performance, see Partitioning and scaling in Azure Cosmos DB.

Performance tips for Azure Cosmos DB and .NET SDK v2

12/4/2020 • 15 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is a fast and flexible distributed database that scales seamlessly with guaranteed latency and throughput. You don't have to make major architecture changes or write complex code to scale your database with Azure Cosmos DB. Scaling up and down is as easy as making a single API call. To learn more, see how to provision container throughput or how to provision database throughput. But because Azure Cosmos DB is accessed via network calls, there are client-side optimizations you can make to achieve peak performance when you use the SQL .NET SDK.

So, if you're trying to improve your database performance, consider these options:

Upgrade to the .NET V3 SDK

The .NET v3 SDK is released. If you use the .NET v3 SDK, see the .NET v3 performance guide for the following information:

- Defaults to Direct TCP mode
- Stream API support
- Support custom serializer to allow System.Text.JSON usage
- Integrated batch and bulk support

Hosting recommendations

For query-intensive workloads, use Windows 64-bit instead of Linux or Windows 32-bit host processing

We recommend Windows 64-bit host processing for improved performance. The SQL SDK includes a native ServiceInterop.dll to parse and optimize queries locally. ServiceInterop.dll is supported only on the Windows x64 platform. For Linux and other unsupported platforms where ServiceInterop.dll isn't available, an additional network call is made to the gateway to get the optimized query. The following types of applications use 32-bit host processing by default. To change host processing to 64-bit processing, follow these steps, based on the type of your application:

- For executable applications, you can change host processing by setting the platform target to **x64** in the **Project Properties** window, on the **Build** tab.
- For VSTest-based test projects, you can change host processing by selecting **Test** > **Test Settings** > **Default Processor Architecture as X64** on the Visual Studio **Test** menu.
- For locally deployed ASP.NET web applications, you can change host processing by selecting **Use the 64-bit version of IIS Express for web sites and projects** under **Tools** > **Options** > **Projects and Solutions** > **Web Projects**.
- For ASP.NET web applications deployed on Azure, you can change host processing by selecting the **64-bit** platform in **Application settings** in the Azure portal.

> **NOTE**
> By default, new Visual Studio projects are set to **Any CPU**. We recommend that you set your project to **x64** so it doesn't switch to **x86**. A project set to **Any CPU** can easily switch to **x86** if an x86-only dependency is added. ServiceInterop.dll needs to be in the folder that the SDK DLL is being executed from. This should be a concern only if you manually copy DLLs or have custom build/deployment systems.

Turn on server-side garbage collection (GC)

Reducing the frequency of garbage collection can help in some cases. In .NET, set gcServer to `true`.

Scale out your client workload

If you're testing at high throughput levels (more than 50,000 RU/s), the client application could become the bottleneck due to the machine capping out on CPU or network utilization. If you reach this point, you can continue to push the Azure Cosmos DB account further by scaling out your client applications across multiple servers.

> **NOTE**
> High CPU usage can cause increased latency and request timeout exceptions.

Networking

Connection policy: Use direct connection mode

.NET V2 SDK default connection mode is gateway. You configure the connection mode during the construction of the `DocumentClient` instance by using the `ConnectionPolicy` parameter. If you use direct mode, you need to also set the `Protocol` by using the `ConnectionPolicy` parameter. To learn more about different connectivity options, see the connectivity modes article.

```
Uri serviceEndpoint = new Uri("https://contoso.documents.net");
string authKey = "your authKey from the Azure portal";
DocumentClient client = new DocumentClient(serviceEndpoint, authKey,
new ConnectionPolicy
{
   ConnectionMode = ConnectionMode.Direct, // ConnectionMode.Gateway is the default
   ConnectionProtocol = Protocol.Tcp
});
```

Ephemeral port exhaustion

If you see a high connection volume or high port usage on your instances, first verify that your client instances are singletons. In other words, the client instances should be unique for the lifetime of the application.

When running on the TCP protocol, the client optimizes for latency by using the long-lived connections as opposed to the HTTPS protocol, which terminates the connections after 2 minutes of inactivity.

In scenarios where you have sparse access and if you notice a higher connection count when compared to the gateway mode access, you can:

- Configure the ConnectionPolicy.PortReuseMode property to `PrivatePortPool` (effective with framework version>= 4.6.1 and .NET core version >= 2.0): This property allows the SDK to use a small pool of ephemeral ports for different Azure Cosmos DB destination endpoints.
- Configure the ConnectionPolicy.IdleConnectionTimeout property must be greater than or equal to 10 minutes. The recommended values are between 20 minutes and 24 hours.

Call OpenAsync to avoid startup latency on first request

By default, the first request has higher latency because it needs to fetch the address routing table. When you use SDK V2, call `OpenAsync()` once during initialization to avoid this startup latency on the first request. The call looks like: `await client.OpenAsync();`

> **NOTE**
>
> `OpenAsync` will generate requests to obtain the address routing table for all the containers in the account. For accounts that have many containers but whose application accesses a subset of them, `OpenAsync` would generate an unnecessary amount of traffic, which would make the initialization slow. So using `OpenAsync` might not be useful in this scenario because it slows down application startup.

For performance, collocate clients in same Azure region

When possible, place any applications that call Azure Cosmos DB in the same region as the Azure Cosmos DB database. Here's an approximate comparison: calls to Azure Cosmos DB within the same region complete within 1 ms to 2 ms, but the latency between the West and East coast of the US is more than 50 ms. This latency can vary from request to request, depending on the route taken by the request as it passes from the client to the Azure datacenter boundary. You can get the lowest possible latency by ensuring the calling application is located within the same Azure region as the provisioned Azure Cosmos DB endpoint. For a list of available regions, see Azure regions.

Increase the number of threads/tasks

Because calls to Azure Cosmos DB are made over the network, you might need to vary the degree of parallelism of your requests so that the client application spends minimal time waiting between requests. For example, if you're using the .NET Task Parallel Library, create on the order of hundreds of tasks that read from or write to Azure Cosmos DB.

Enable accelerated networking

To reduce latency and CPU jitter, we recommend that you enable accelerated networking on client virtual machines. See Create a Windows virtual machine with accelerated networking or Create a Linux virtual machine with accelerated networking.

SDK usage

Install the most recent SDK

The Azure Cosmos DB SDKs are constantly being improved to provide the best performance. See the Azure Cosmos DB SDK pages to determine the most recent SDK and review improvements.

Use a singleton Azure Cosmos DB client for the lifetime of your application

Each `DocumentClient` instance is thread-safe and performs efficient connection management and address caching when operating in direct mode. To allow efficient connection management and better SDK client performance, we recommend that you use a single instance per `AppDomain` for the lifetime of the application.

Increase System.Net MaxConnections per host when using gateway mode

Azure Cosmos DB requests are made over HTTPS/REST when you use gateway mode. They're subjected to the default connection limit per hostname or IP address. You might need to set `MaxConnections` to a higher value (100 to 1,000) so the client library can use multiple simultaneous connections to Azure Cosmos DB. In .NET SDK 1.8.0 and later, the default value for ServicePointManager.DefaultConnectionLimit is 50. To change the value, you can set Documents.Client.ConnectionPolicy.MaxConnectionLimit to a higher value.

Tune parallel queries for partitioned collections

SQL .NET SDK 1.9.0 and later support parallel queries, which enable you to query a partitioned collection in parallel. For more information, see code samples related to working with the SDKs. Parallel queries are designed to provide better query latency and throughput than their serial counterpart. Parallel queries provide two parameters that you can tune to fit your requirements:

- `MaxDegreeOfParallelism` controls the maximum number of partitions that can be queried in parallel.
- `MaxBufferedItemCount` controls the number of pre-fetched results.

Tuning degree of parallelism

Parallel query works by querying multiple partitions in parallel. But data from an individual partition is fetched serially with respect to the query. Setting `MaxDegreeOfParallelism` in SDK V2 to the number of partitions has the best chance of achieving the most performant query, provided all other system conditions remain the same. If you don't know the number of partitions, you can set the degree of parallelism to a high number. The system will choose the minimum (number of partitions, user provided input) as the degree of parallelism.

Parallel queries produce the most benefit if the data is evenly distributed across all partitions with respect to the query. If the partitioned collection is partitioned so that all or most of the data returned by a query is concentrated in a few partitions (one partition is the worst case), those partitions will bottleneck the performance of the query.

Tuning MaxBufferedItemCount

Parallel query is designed to pre-fetch results while the current batch of results is being processed by the client. This pre-fetching helps improve the overall latency of a query. The `MaxBufferedItemCount` parameter limits the number of pre-fetched results. Set `MaxBufferedItemCount` to the expected number of results returned (or a higher number) to allow the query to receive the maximum benefit from pre-fetching.

Pre-fetching works the same way regardless of the degree of parallelism, and there's a single buffer for the data from all partitions.

Implement backoff at RetryAfter intervals

During performance testing, you should increase load until a small rate of requests are throttled. If requests are throttled, the client application should back off on throttle for the server-specified retry interval. Respecting the backoff ensures you spend a minimal amount of time waiting between retries.

Retry policy support is included in these SDKs:

- Version 1.8.0 and later of the .NET SDK for SQL and the Java SDK for SQL
- Version 1.9.0 and later of the Node.js SDK for SQL and the Python SDK for SQL
- All supported versions of the .NET Core SDKs

For more information, see RetryAfter.

In version 1.19 and later of the .NET SDK, there's a mechanism for logging additional diagnostic information and troubleshooting latency issues, as shown in the following sample. You can log the diagnostic string for requests that have a higher read latency. The captured diagnostic string will help you understand how many times you received 429 errors for a given request.

```
ResourceResponse<Document> readDocument = await
this.readClient.ReadDocumentAsync(oldDocuments[i].SelfLink);
readDocument.RequestDiagnosticsString
```

Cache document URIs for lower read latency

Cache document URIs whenever possible for the best read performance. You need to define logic to cache the resource ID when you create a resource. Lookups based on resource IDs are faster than name-based lookups, so caching these values improves performance.

Tune the page size for queries/read feeds for better performance

When you do a bulk read of documents by using read feed functionality (for example, `ReadDocumentFeedAsync`) or when you issue a SQL query, the results are returned in a segmented fashion if the result set is too large. By default, results are returned in chunks of 100 items or 1 MB, whichever limit is hit first.

To reduce the number of network round trips required to retrieve all applicable results, you can increase the page size by using x-ms-max-item-count to request as many as 1,000 headers. When you need to display only a few results, for example, if your user interface or application API returns only 10 results at a time, you can also decrease the page size to 10 to reduce the throughput consumed for reads and queries.

> **NOTE**
> The `maxItemCount` property shouldn't be used just for pagination. Its main use is to improve the performance of queries by reducing the maximum number of items returned in a single page.

You can also set the page size by using the available Azure Cosmos DB SDKs. The MaxItemCount property in `FeedOptions` allows you to set the maximum number of items to be returned in the enumeration operation. When `maxItemCount` is set to -1, the SDK automatically finds the optimal value, depending on the document size. For example:

```
IQueryable<dynamic> authorResults = client.CreateDocumentQuery(documentCollection.SelfLink, "SELECT
p.Author FROM Pages p WHERE p.Title = 'About Seattle'", new FeedOptions { MaxItemCount = 1000 });
```

When a query is executed, the resulting data is sent within a TCP packet. If you specify too low a value for `maxItemCount`, the number of trips required to send the data within the TCP packet is high, which affects performance. So if you're not sure what value to set for the `maxItemCount` property, it's best to set it to -1 and let the SDK choose the default value.

Increase the number of threads/tasks

See Increase the number of threads/tasks in the networking section of this article.

Indexing policy

Exclude unused paths from indexing for faster writes

The Azure Cosmos DB indexing policy also allows you to specify which document paths to include in or exclude

from indexing by using indexing paths (IndexingPolicy.IncludedPaths and IndexingPolicy.ExcludedPaths). Indexing paths can improve write performance and reduce index storage for scenarios in which the query patterns are known beforehand. This is because indexing costs correlate directly to the number of unique paths indexed. For example, this code shows how to exclude an entire section of the documents (a subtree) from indexing by using the "*" wildcard:

```
var collection = new DocumentCollection { Id = "excludedPathCollection" };
collection.IndexingPolicy.IncludedPaths.Add(new IncludedPath { Path = "/*" });
collection.IndexingPolicy.ExcludedPaths.Add(new ExcludedPath { Path = "/nonIndexedContent/*");
collection = await client.CreateDocumentCollectionAsync(UriFactory.CreateDatabaseUri("db"), collection);
```

For more information, see Azure Cosmos DB indexing policies.

Throughput

Measure and tune for lower Request Units/second usage

Azure Cosmos DB offers a rich set of database operations. These operations include relational and hierarchical queries with UDFs, stored procedures, and triggers, all operating on the documents within a database collection. The cost associated with each of these operations varies depending on the CPU, IO, and memory required to complete the operation. Instead of thinking about and managing hardware resources, you can think of a Request Unit (RU) as a single measure for the resources required to perform various database operations and service an application request.

Throughput is provisioned based on the number of Request Units set for each container. Request Unit consumption is evaluated as a rate per second. Applications that exceed the provisioned Request Unit rate for their container are limited until the rate drops below the provisioned level for the container. If your application requires a higher level of throughput, you can increase your throughput by provisioning additional Request Units.

The complexity of a query affects how many Request Units are consumed for an operation. The number of predicates, the nature of the predicates, the number of UDFs, and the size of the source dataset all influence the cost of query operations.

To measure the overhead of any operation (create, update, or delete), inspect the x-ms-request-charge header (or the equivalent `RequestCharge` property in `ResourceResponse\<T>` or `FeedResponse\<T>` in the .NET SDK) to measure the number of Request Units consumed by the operations:

```
// Measure the performance (Request Units) of writes
ResourceResponse<Document> response = await client.CreateDocumentAsync(collectionSelfLink, myDocument);
Console.WriteLine("Insert of document consumed {0} request units", response.RequestCharge);
// Measure the performance (Request Units) of queries
IDocumentQuery<dynamic> queryable = client.CreateDocumentQuery(collectionSelfLink,
queryString).AsDocumentQuery();
while (queryable.HasMoreResults)
    {
        FeedResponse<dynamic> queryResponse = await queryable.ExecuteNextAsync<dynamic>();
        Console.WriteLine("Query batch consumed {0} request units", queryResponse.RequestCharge);
    }
```

The request charge returned in this header is a fraction of your provisioned throughput (that is, 2,000 RUs / second). For example, if the preceding query returns 1,000 1-KB documents, the cost of the operation is 1,000. So, within one second, the server honors only two such requests before rate limiting later requests. For more information, see Request Units and the Request Unit calculator.

Handle rate limiting/request rate too large

When a client attempts to exceed the reserved throughput for an account, there's no performance degradation at the server and no use of throughput capacity beyond the reserved level. The server will preemptively end the request with RequestRateTooLarge (HTTP status code 429). It will return an x-ms-retry-after-ms header that indicates the amount of time, in milliseconds, that the user must wait before attempting the request again.

```
HTTP Status 429,
Status Line: RequestRateTooLarge
x-ms-retry-after-ms :100
```

The SDKs all implicitly catch this response, respect the server-specified retry-after header, and retry the request. Unless your account is being accessed concurrently by multiple clients, the next retry will succeed.

If you have more than one client cumulatively operating consistently above the request rate, the default retry count currently set to 9 internally by the client might not suffice. In this case, the client throws a DocumentClientException with status code 429 to the application.

You can change the default retry count by setting the `RetryOptions` on the `ConnectionPolicy` instance. By default, the DocumentClientException with status code 429 is returned after a cumulative wait time of 30 seconds if the request continues to operate above the request rate. This error returns even when the current retry count is less than the maximum retry count, whether the current value is the default of 9 or a user-defined value.

The automated retry behavior helps improve resiliency and usability for most applications. But it might not be the best behavior when you're doing performance benchmarks, especially when you're measuring latency. The client-observed latency will spike if the experiment hits the server throttle and causes the client SDK to silently retry. To avoid latency spikes during performance experiments, measure the charge returned by each operation and ensure that requests are operating below the reserved request rate. For more information, see Request Units.

For higher throughput, design for smaller documents

The request charge (that is, the request-processing cost) of a given operation correlates directly to the size of the document. Operations on large documents cost more than operations on small documents.

Next steps

For a sample application that's used to evaluate Azure Cosmos DB for high-performance scenarios on a few client machines, see Performance and scale testing with Azure Cosmos DB.

To learn more about designing your application for scale and high performance, see Partitioning and scaling in Azure Cosmos DB.

Performance tips for Azure Cosmos DB Java SDK v4

12/4/2020 • 21 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> The performance tips in this article are for Azure Cosmos DB Java SDK v4 only. Please view the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, and Azure Cosmos DB Java SDK v4 troubleshooting guide for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

Azure Cosmos DB is a fast and flexible distributed database that scales seamlessly with guaranteed latency and throughput. You do not have to make major architecture changes or write complex code to scale your database with Azure Cosmos DB. Scaling up and down is as easy as making a single API call or SDK method call. However, because Azure Cosmos DB is accessed via network calls there are client-side optimizations you can make to achieve peak performance when using Azure Cosmos DB Java SDK v4.

So if you're asking "How can I improve my database performance?" consider the following options:

Networking

- **Connection mode: Use Direct mode**

  Java SDK default connection mode is direct. You can configure the connection mode in the client builder using the *directMode()* or *gatewayMode()* methods, as shown below. To configure either mode with default settings, call either method without arguments. Otherwise, pass a configuration settings class instance as the argument (*DirectConnectionConfig* for *directMode()*, *GatewayConnectionConfig* for *gatewayMode()*.). To learn more about different connectivity options, see the connectivity modes article.

  Java V4 SDK

  - Async
  - Sync

  Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
/* Direct mode, default settings */
CosmosAsyncClient clientDirectDefault = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .directMode()
        .buildAsyncClient();

/* Direct mode, custom settings */
DirectConnectionConfig directConnectionConfig = DirectConnectionConfig.getDefaultConfig();

// Example config, do not use these settings as defaults
directConnectionConfig.setMaxConnectionsPerEndpoint(120);
directConnectionConfig.setIdleConnectionTimeout(Duration.ofMillis(100));

CosmosAsyncClient clientDirectCustom = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .directMode(directConnectionConfig)
        .buildAsyncClient();

/* Gateway mode, default settings */
CosmosAsyncClient clientGatewayDefault = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .gatewayMode()
        .buildAsyncClient();

/* Gateway mode, custom settings */
GatewayConnectionConfig gatewayConnectionConfig = GatewayConnectionConfig.getDefaultConfig();

// Example config, do not use these settings as defaults
gatewayConnectionConfig.setProxy(new ProxyOptions(ProxyOptions.Type.HTTP,
InetSocketAddress.createUnresolved("your.proxy.addr",80)));
gatewayConnectionConfig.setMaxConnectionPoolSize(150);

CosmosAsyncClient clientGatewayCustom = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .gatewayMode(gatewayConnectionConfig)
        .buildAsyncClient();

/* No connection mode, defaults to Direct mode with default settings */
CosmosAsyncClient clientDefault = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .buildAsyncClient();
```

The *directMode()* method has an additional override, for the following reason. Control plane operations such as database and container CRUD *always* utilize Gateway mode; when the user has configured Direct mode for data plane operations, control plane operations use default Gateway mode settings. This suits most users. However, users who want Direct mode for data plane operations as well as tunability of control plane Gateway mode parameters can use the following *directMode()* override:

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
/* Independent customization of Direct mode data plane and Gateway mode control plane */
DirectConnectionConfig directConnectionConfig = DirectConnectionConfig.getDefaultConfig();

// Example config, do not use these settings as defaults
directConnectionConfig.setMaxConnectionsPerEndpoint(120);
directConnectionConfig.setIdleConnectionTimeout(Duration.ofMillis(100));

GatewayConnectionConfig gatewayConnectionConfig = GatewayConnectionConfig.getDefaultConfig();

// Example config, do not use these settings as defaults
gatewayConnectionConfig.setProxy(new ProxyOptions(ProxyOptions.Type.HTTP,
InetSocketAddress.createUnresolved("your.proxy.addr",80)));
gatewayConnectionConfig.setMaxConnectionPoolSize(150);

CosmosAsyncClient clientDirectCustom = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .directMode(directConnectionConfig,gatewayConnectionConfig)
        .buildAsyncClient();
```

- **Collocate clients in same Azure region for performance**

  When possible, place any applications calling Azure Cosmos DB in the same region as the Azure Cosmos database. For an approximate comparison, calls to Azure Cosmos DB within the same region complete within 1-2 ms, but the latency between the West and East coast of the US is >50 ms. This latency can likely vary from request to request depending on the route taken by the request as it passes from the client to the Azure datacenter boundary. The lowest possible latency is achieved by ensuring the calling application is located within the same Azure region as the provisioned Azure Cosmos DB endpoint. For a list of available regions, see Azure Regions.

  An app that interacts with a multi-region Azure Cosmos DB account needs to configure preferred locations to ensure that requests are going to a collocated region.

- **Enable Accelerated Networking on your Azure VM for lower latency.**

It is recommended that you follow the instructions to enable Accelerated Networking in your Windows (click for instructions) or Linux (click for instructions) Azure VM, in order to maximize performance.

Without accelerated networking, IO that transits between your Azure VM and other Azure resources may be unnecessarily routed through a host and virtual switch situated between the VM and its network card. Having the host and virtual switch inline in the datapath not only increases latency and jitter in the communication channel, it also steals CPU cycles from the VM. With accelerated networking, the VM interfaces directly with the

NIC without intermediaries; any network policy details which were being handled by the host and virtual switch are now handled in hardware at the NIC; the host and virtual switch are bypassed. Generally you can expect lower latency and higher throughput, as well as more *consistent* latency and decreased CPU utilization when you enable accelerated networking.

Limitations: accelerated networking must be supported on the VM OS, and can only be enabled when the VM is stopped and deallocated. The VM cannot be deployed with Azure Resource Manager.

Please see the Windows and Linux instructions for more details.

SDK usage

- **Install the most recent SDK**

  The Azure Cosmos DB SDKs are constantly being improved to provide the best performance. See the Azure Cosmos DB SDK pages to determine the most recent SDK and review improvements.

- **Use a singleton Azure Cosmos DB client for the lifetime of your application**

  Each Azure Cosmos DB client instance is thread-safe and performs efficient connection management and address caching. To allow efficient connection management and better performance by the Azure Cosmos DB client, it is recommended to use a single instance of the Azure Cosmos DB client per AppDomain for the lifetime of the application.

- **Use the lowest consistency level required for your application**

  When you create a *CosmosClient*, the default consistency used if not explicitly set is *Session*. If *Session* consistency is not required by your application logic set the *Consistency* to *Eventual*. Note: it is recommended to use at least *Session* consistency in applications employing the Azure Cosmos DB Change Feed processor.

- **Use Async API to max out provisioned throughput**

  Azure Cosmos DB Java SDK v4 bundles two APIs, Sync and Async. Roughly speaking, the Async API implements SDK functionality, whereas the Sync API is a thin wrapper that makes blocking calls to the Async API. This stands in contrast to the older Azure Cosmos DB Async Java SDK v2, which was Async-only, and to the older Azure Cosmos DB Sync Java SDK v2, which was Sync-only and had a completely separate implementation.

  The choice of API is determined during client initialization; a *CosmosAsyncClient* supports Async API while a *CosmosClient* supports Sync API.

  The Async API implements non-blocking IO and is the optimal choice if your goal is to max out throughput when issuing requests to Azure Cosmos DB.

  Using Sync API can be the right choice if you want or need an API which blocks on the response to each request, or if synchronous operation is the dominant paradigm in your application. For example, you might want the Sync API when you are persisting data to Azure Cosmos DB in a microservices application, provided throughput is not critical.

  Just be aware that Sync API throughput degrades with increasing request response-time, whereas the Async API can saturate the full bandwidth capabilities of your hardware.

  Geographic collocation can give you higher and more consistent throughput when using Sync API (see Collocate clients in same Azure region for performance) but still is not expected to exceed Async API attainable throughput.

  Some users may also be unfamiliar with Project Reactor, the Reactive Streams framework used to implement Azure Cosmos DB Java SDK v4 Async API. If this is a concern, we recommend you read our

introductory Reactor Pattern Guide and then take a look at this Introduction to Reactive Programming in order to familiarize yourself. If you have already used Azure Cosmos DB with an Async interface, and the SDK you used was Azure Cosmos DB Async Java SDK v2, then you may be familiar with ReactiveX/RxJava but be unsure what has changed in Project Reactor. In that case, please take a look at our Reactor vs. RxJava Guide to become familiarized.

The following code snippets show how to initialize your Azure Cosmos DB client for Async API or Sync API operation, respectively:

Java V4 SDK

- Async
- Sync

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
CosmosAsyncClient client = new CosmosClientBuilder()
        .endpoint(HOSTNAME)
        .key(MASTERKEY)
        .consistencyLevel(CONSISTENCY)
        .buildAsyncClient();
```

- Tuning ConnectionPolicy

  By default, Direct mode Cosmos DB requests are made over TCP when using Azure Cosmos DB Java SDK v4. Internally Direct mode uses a special architecture to dynamically manage network resources and get the best performance.

  In Azure Cosmos DB Java SDK v4, Direct mode is the best choice to improve database performance with most workloads.

  - *Overview of Direct mode*

The client-side architecture employed in Direct mode enables predictable network utilization and multiplexed access to Azure Cosmos DB replicas. The diagram above shows how Direct mode routes client requests to replicas in the Cosmos DB backend. The Direct mode architecture allocates up to 10 **Channels** on the client side per DB replica. A Channel is a TCP connection preceded by a request buffer, which is 30 requests deep. The Channels belonging to a replica are dynamically allocated as needed by the replica's **Service Endpoint**. When the user issues a request in Direct mode, the **TransportClient** routes the request to the proper service endpoint based on the partition key. The **Request Queue** buffers requests before the Service Endpoint.

- ***Configuration options for Direct mode***

  If non-default Direct mode behavior is desired, create a *DirectConnectionConfig* instance and customize its properties, then pass the customized property instance to the *directMode()* method in the Azure Cosmos DB client builder.

  These configuration settings control the behavior of the underlying Direct mode architecture discussed above.

  As a first step, use the following recommended configuration settings below. These *DirectConnectionConfig* options are advanced configuration settings which can affect SDK performance in unexpected ways; we recommend users avoid modifying them unless they feel very comfortable in understanding the tradeoffs and it is absolutely necessary. Please contact the Azure Cosmos DB team if you run into issues on this particular topic.

CONFIGURATION OPTION	DEFAULT
idleConnectionTimeout	"PT0"
maxConnectionsPerEndpoint	"130"

CONFIGURATION OPTION	DEFAULT
connectTimeout	"PT5S"
idleEndpointTimeout	"PT1H"
maxRequestsPerConnection	"30"

- **Tuning parallel queries for partitioned collections**

  Azure Cosmos DB Java SDK v4 supports parallel queries, which enable you to query a partitioned collection in parallel. For more information, see code samples related to working with Azure Cosmos DB Java SDK v4. Parallel queries are designed to improve query latency and throughput over their serial counterpart.

  - ***Tuning setMaxDegreeOfParallelism:***

    Parallel queries work by querying multiple partitions in parallel. However, data from an individual partitioned collection is fetched serially with respect to the query. So, use setMaxDegreeOfParallelism to set the number of partitions that has the maximum chance of achieving the most performant query, provided all other system conditions remain the same. If you don't know the number of partitions, you can use setMaxDegreeOfParallelism to set a high number, and the system chooses the minimum (number of partitions, user provided input) as the maximum degree of parallelism.

    It is important to note that parallel queries produce the best benefits if the data is evenly distributed across all partitions with respect to the query. If the partitioned collection is partitioned such a way that all or a majority of the data returned by a query is concentrated in a few partitions (one partition in worst case), then the performance of the query would be bottlenecked by those partitions.

  - ***Tuning setMaxBufferedItemCount:***

    Parallel query is designed to pre-fetch results while the current batch of results is being processed by the client. The pre-fetching helps in overall latency improvement of a query. setMaxBufferedItemCount limits the number of pre-fetched results. Setting setMaxBufferedItemCount to the expected number of results returned (or a higher number) enables the query to receive maximum benefit from pre-fetching.

    Pre-fetching works the same way irrespective of the MaxDegreeOfParallelism, and there is a single buffer for the data from all partitions.

- **Scale out your client-workload**

  If you are testing at high throughput levels, the client application may become the bottleneck due to the machine capping out on CPU or network utilization. If you reach this point, you can continue to push the Azure Cosmos DB account further by scaling out your client applications across multiple servers.

  A good rule of thumb is not to exceed >50% CPU utilization on any given server, to keep latency low.

- **Tune the page size for queries/read feeds for better performance**

  When performing a bulk read of documents by using read feed functionality (for example, *readItems*) or when issuing a SQL query (*queryItems*), the results are returned in a segmented fashion if the result set is too large. By default, results are returned in chunks of 100 items or 1 MB, whichever limit is hit first.

  Suppose that your application issues a query to Azure Cosmos DB, and suppose that your application requires the full set of query results in order to complete its task. To reduce the number of network

round trips required to retrieve all applicable results, you can increase the page size by adjusting the x-ms-max-item-count request header field.

- For single-partition queries, adjusting the x-ms-max-item-count field value to -1 (no limit on page size) maximizes latency by minimizing the number of query response pages: either the full result set will return in a single page, or if the query takes longer than the timeout interval, then the full result set will be returned in the minimum number of pages possible. This saves on multiples of the request round-trip time.
- For cross-partition queries, setting the x-ms-max-item-count field to -1 and removing the page size limit risks overwhelming the SDK with unmanageable page sizes. In the cross-partition case we recommend raising the page size limit up to some large but finite value, perhaps 1000, to reduce latency.

In some applications, you may not require the full set of query results. In cases where you need to display only a few results, for example, if your user interface or application API returns only 10 results at a time, you can also decrease the page size to 10 to reduce the throughput consumed for reads and queries.

You may also set the preferred page size argument of the *byPage* method, rather than modifying the REST header field directly. Keep in mind that x-ms-max-item-count or the preferred page size argument of *byPage* are only setting an upper limit on page size, not an absolute requirement; so for a variety of reason you may see Azure Cosmos DB return pages which are smaller than your preferred page size.

- **Use Appropriate Scheduler (Avoid stealing Event loop IO Netty threads)**

  The asynchronous functionality of Azure Cosmos DB Java SDK is based on netty non-blocking IO. The SDK uses a fixed number of IO netty event loop threads (as many CPU cores your machine has) for executing IO operations. The Flux returned by API emits the result on one of the shared IO event loop netty threads. So it is important to not block the shared IO event loop netty threads. Doing CPU intensive work or blocking operation on the IO event loop netty thread may cause deadlock or significantly reduce SDK throughput.

  For example the following code executes a cpu intensive work on the event loop IO netty thread:

  Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
Mono<CosmosItemResponse<CustomPOJO>> createItemPub = asyncContainer.createItem(item);
createItemPub.subscribe(
        itemResponse -> {
            //this is executed on eventloop IO netty thread.
            //the eventloop thread is shared and is meant to return back quickly.
            //
            // DON'T do this on eventloop IO netty thread.
            veryCpuIntensiveWork();
        });
```

  After result is received if you want to do CPU intensive work on the result you should avoid doing so on event loop IO netty thread. You can instead provide your own Scheduler to provide your own thread for running your work, as shown below (requires `import reactor.core.scheduler.Schedulers`).

  Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
Mono<CosmosItemResponse<CustomPOJO>> createItemPub = asyncContainer.createItem(item);
createItemPub
        .subscribeOn(Schedulers.elastic())
        .subscribe(
                itemResponse -> {
                    //this is executed on eventloop IO netty thread.
                    //the eventloop thread is shared and is meant to return back quickly.
                    //
                    // DON'T do this on eventloop IO netty thread.
                    veryCpuIntensiveWork();
                });
```

Based on the type of your work you should use the appropriate existing Reactor Scheduler for your work. Read here `Schedulers`.

For more information on Azure Cosmos DB Java SDK v4, please look at the Cosmos DB directory of the Azure SDK for Java monorepo on GitHub.

- **Optimize logging settings in your application**

  For a variety of reasons, you may want or need to add logging in a thread which is generating high request throughput. If your goal is to fully saturate a container's provisioned throughput with requests generated by this thread, logging optimizations can greatly improve performance.

  - ***Configure an async logger***

    The latency of a synchronous logger necessarily factors into the overall latency calculation of your request-generating thread. An async logger such as log4j2 is recommended to decouple logging overhead from your high-performance application threads.

  - ***Disable netty's logging***

    Netty library logging is chatty and needs to be turned off (suppressing sign in the configuration may not be enough) to avoid additional CPU costs. If you are not in debugging mode, disable netty's logging altogether. So if you are using log4j to remove the additional CPU costs incurred by `org.apache.log4j.Category.callAppenders()` from netty add the following line to your codebase:

    ```
    org.apache.log4j.Logger.getLogger("io.netty").setLevel(org.apache.log4j.Level.OFF);
    ```

- **OS Open files Resource Limit**

  Some Linux systems (like Red Hat) have an upper limit on the number of open files and so the total number of connections. Run the following to view the current limits:

  ```
  ulimit -a
  ```

  The number of open files (nofile) needs to be large enough to have enough room for your configured connection pool size and other open files by the OS. It can be modified to allow for a larger connection pool size.

  Open the limits.conf file:

  ```
  vim /etc/security/limits.conf
  ```

Add/modify the following lines:

```
* - nofile 100000
```

- **Specify partition key in point writes**

  To improve the performance of point writes, specify item partition key in the point write API call, as shown below:

  - Async
  - Sync

  Java SDK V4 (Maven com.azure::azure-cosmos) Async API

  ```
  asyncContainer.createItem(item,new PartitionKey(pk),new CosmosItemRequestOptions()).block();
  ```

  rather than providing only the item instance, as shown below:

  - Async
  - Sync

  Java SDK V4 (Maven com.azure::azure-cosmos) Async API

  ```
  asyncContainer.createItem(item).block();
  ```

  The latter is supported but will add latency to your application; the SDK must parse the item and extract the partition key.

Indexing policy

- **Exclude unused paths from indexing for faster writes**

  Azure Cosmos DB's indexing policy allows you to specify which document paths to include or exclude from indexing by leveraging Indexing Paths (setIncludedPaths and setExcludedPaths). The use of indexing paths can offer improved write performance and lower index storage for scenarios in which the query patterns are known beforehand, as indexing costs are directly correlated to the number of unique paths indexed. For example, the following code shows how to include and exclude entire sections of the documents (also known as a subtree) from indexing using the "*" wildcard.

  Java SDK V4 (Maven com.azure::azure-cosmos)

```
CosmosContainerProperties containerProperties = new CosmosContainerProperties(containerName,
"/lastName");

// Custom indexing policy
IndexingPolicy indexingPolicy = new IndexingPolicy();
indexingPolicy.setIndexingMode(IndexingMode.CONSISTENT);

// Included paths
List<IncludedPath> includedPaths = new ArrayList<>();
includedPaths.add(new IncludedPath("/*"));
indexingPolicy.setIncludedPaths(includedPaths);

// Excluded paths
List<ExcludedPath> excludedPaths = new ArrayList<>();
excludedPaths.add(new ExcludedPath("/name/*"));
indexingPolicy.setExcludedPaths(excludedPaths);

containerProperties.setIndexingPolicy(indexingPolicy);

ThroughputProperties throughputProperties = ThroughputProperties.createManualThroughput(400);

database.createContainerIfNotExists(containerProperties, throughputProperties);
CosmosAsyncContainer containerIfNotExists = database.getContainer(containerName);
```

For more information, see Azure Cosmos DB indexing policies.

Throughput

- **Measure and tune for lower request units/second usage**

  Azure Cosmos DB offers a rich set of database operations including relational and hierarchical queries with UDFs, stored procedures, and triggers – all operating on the documents within a database collection. The cost associated with each of these operations varies based on the CPU, IO, and memory required to complete the operation. Instead of thinking about and managing hardware resources, you can think of a request unit (RU) as a single measure for the resources required to perform various database operations and service an application request.

  Throughput is provisioned based on the number of request units set for each container. Request unit consumption is evaluated as a rate per second. Applications that exceed the provisioned request unit rate for their container are limited until the rate drops below the provisioned level for the container. If your application requires a higher level of throughput, you can increase your throughput by provisioning additional request units.

  The complexity of a query impacts how many request units are consumed for an operation. The number of predicates, nature of the predicates, number of UDFs, and the size of the source data set all influence the cost of query operations.

  To measure the overhead of any operation (create, update, or delete), inspect the x-ms-request-charge header to measure the number of request units consumed by these operations. You can also look at the equivalent RequestCharge property in ResourceResponse<T> or FeedResponse<T>.

  - Async
  - Sync

  Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
CosmosItemResponse<CustomPOJO> response = asyncContainer.createItem(item).block();

response.getRequestCharge();
```

The request charge returned in this header is a fraction of your provisioned throughput. For example, if you have 2000 RU/s provisioned, and if the preceding query returns 1000 1KB-documents, the cost of the operation is 1000. As such, within one second, the server honors only two such requests before rate limiting subsequent requests. For more information, see Request units and the request unit calculator.

- **Handle rate limiting/request rate too large**

  When a client attempts to exceed the reserved throughput for an account, there is no performance degradation at the server and no use of throughput capacity beyond the reserved level. The server will preemptively end the request with RequestRateTooLarge (HTTP status code 429) and return the x-ms-retry-after-ms header indicating the amount of time, in milliseconds, that the user must wait before reattempting the request.

  ```
  HTTP Status 429,
  Status Line: RequestRateTooLarge
  x-ms-retry-after-ms :100
  ```

  The SDKs all implicitly catch this response, respect the server-specified retry-after header, and retry the request. Unless your account is being accessed concurrently by multiple clients, the next retry will succeed.

  If you have more than one client cumulatively operating consistently above the request rate, the default retry count currently set to 9 internally by the client may not suffice; in this case, the client throws a *CosmosClientException* with status code 429 to the application. The default retry count can be changed by using setRetryOptions on the ConnectionPolicy instance. By default, the *CosmosClientException* with status code 429 is returned after a cumulative wait time of 30 seconds if the request continues to operate above the request rate. This occurs even when the current retry count is less than the max retry count, be it the default of 9 or a user-defined value.

  While the automated retry behavior helps to improve resiliency and usability for the most applications, it might come at odds when doing performance benchmarks, especially when measuring latency. The client-observed latency will spike if the experiment hits the server throttle and causes the client SDK to silently retry. To avoid latency spikes during performance experiments, measure the charge returned by each operation and ensure that requests are operating below the reserved request rate. For more information, see Request units.

- **Design for smaller documents for higher throughput**

  The request charge (the request processing cost) of a given operation is directly correlated to the size of the document. Operations on large documents cost more than operations for small documents. Ideally, architect your application and workflows to have your item size be ~1KB, or similar order or magnitude. For latency-sensitive applications large items should be avoided - multi-MB documents will slow down your application.

Performance tips for Azure Cosmos DB Async Java SDK v2

12/4/2020 • 15 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> This is *not* the latest Java SDK for Azure Cosmos DB! You should upgrade your project to Azure Cosmos DB Java SDK v4 and then read the Azure Cosmos DB Java SDK v4 performance tips guide. Follow the instructions in the Migrate to Azure Cosmos DB Java SDK v4 guide and Reactor vs RxJava guide to upgrade.
>
> The performance tips in this article are for Azure Cosmos DB Async Java SDK v2 only. See the Azure Cosmos DB Async Java SDK v2 Release notes, Maven repository, and Azure Cosmos DB Async Java SDK v2 troubleshooting guide for more information.

Azure Cosmos DB is a fast and flexible distributed database that scales seamlessly with guaranteed latency and throughput. You do not have to make major architecture changes or write complex code to scale your database with Azure Cosmos DB. Scaling up and down is as easy as making a single API call or SDK method call. However, because Azure Cosmos DB is accessed via network calls there are client-side optimizations you can make to achieve peak performance when using the Azure Cosmos DB Async Java SDK v2.

So if you're asking "How can I improve my database performance?" consider the following options:

Networking

- **Connection mode: Use Direct mode**

  How a client connects to Azure Cosmos DB has important implications on performance, especially in terms of client-side latency. The *ConnectionMode* is a key configuration setting available for configuring the client *ConnectionPolicy*. For Azure Cosmos DB Async Java SDK v2, the two available ConnectionModes are:

  - Gateway (default)
  - Direct

  Gateway mode is supported on all SDK platforms and it is the configured option by default. If your applications run within a corporate network with strict firewall restrictions, Gateway mode is the best choice since it uses the standard HTTPS port and a single endpoint. The performance tradeoff, however, is that Gateway mode involves an additional network hop every time data is read or written to Azure Cosmos DB. Because of this, Direct mode offers better performance due to fewer network hops.

  The *ConnectionMode* is configured during the construction of the *DocumentClient* instance with the *ConnectionPolicy* parameter.

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
    public ConnectionPolicy getConnectionPolicy() {
        ConnectionPolicy policy = new ConnectionPolicy();
        policy.setConnectionMode(ConnectionMode.Direct);
        policy.setMaxPoolSize(1000);
        return policy;
    }

    ConnectionPolicy connectionPolicy = new ConnectionPolicy();
    DocumentClient client = new DocumentClient(HOST, MASTER_KEY, connectionPolicy, null);
```

- **Collocate clients in same Azure region for performance**

  When possible, place any applications calling Azure Cosmos DB in the same region as the Azure Cosmos database. For an approximate comparison, calls to Azure Cosmos DB within the same region complete within 1-2 ms, but the latency between the West and East coast of the US is >50 ms. This latency can likely vary from request to request depending on the route taken by the request as it passes from the client to the Azure datacenter boundary. The lowest possible latency is achieved by ensuring the calling application is located within the same Azure region as the provisioned Azure Cosmos DB endpoint. For a list of available regions, see Azure Regions.

SDK Usage

- **Install the most recent SDK**

  The Azure Cosmos DB SDKs are constantly being improved to provide the best performance. See the Azure Cosmos DB Async Java SDK v2 Release Notes pages to determine the most recent SDK and review improvements.

- **Use a singleton Azure Cosmos DB client for the lifetime of your application**

  Each AsyncDocumentClient instance is thread-safe and performs efficient connection management and address caching. To allow efficient connection management and better performance by AsyncDocumentClient, it is recommended to use a single instance of AsyncDocumentClient per AppDomain for the lifetime of the application.

- **Tuning ConnectionPolicy**

  By default, Direct mode Cosmos DB requests are made over TCP when using the Azure Cosmos DB Async Java SDK v2. Internally the SDK uses a special Direct mode architecture to dynamically manage network resources and get the best performance.

  In the Azure Cosmos DB Async Java SDK v2, Direct mode is the best choice to improve database performance with most workloads.

  - *Overview of Direct mode*

The client-side architecture employed in Direct mode enables predictable network utilization and multiplexed access to Azure Cosmos DB replicas. The diagram above shows how Direct mode routes client requests to replicas in the Cosmos DB backend. The Direct mode architecture allocates up to 10 **Channels** on the client side per DB replica. A Channel is a TCP connection preceded by a request buffer, which is 30 requests deep. The Channels belonging to a replica are dynamically allocated as needed by the replica's **Service Endpoint**. When the user issues a request in Direct mode, the **TransportClient** routes the request to the proper service endpoint based on the partition key. The **Request Queue** buffers requests before the Service Endpoint.

- *ConnectionPolicy Configuration options for Direct mode*

  As a first step, use the following recommended configuration settings below. Please contact the Azure Cosmos DB team if you run into issues on this particular topic.

  If you are using Azure Cosmos DB as a reference database (that is, the database is used for many point read operations and few write operations), it may be acceptable to set *idleEndpointTimeout* to 0 (that is, no timeout).

CONFIGURATION OPTION	DEFAULT
bufferPageSize	8192
connectionTimeout	"PT1M"
idleChannelTimeout	"PT0S"
idleEndpointTimeout	"PT1M10S"
maxBufferCapacity	8388608

CONFIGURATION OPTION	DEFAULT
maxChannelsPerEndpoint	10
maxRequestsPerChannel	30
receiveHangDetectionTime	"PT1M5S"
requestExpiryInterval	"PT5S"
requestTimeout	"PT1M"
requestTimerResolution	"PT0.5S"
sendHangDetectionTime	"PT10S"
shutdownTimeout	"PT15S"

- ***Programming tips for Direct mode***

  Review the Azure Cosmos DB Async Java SDK v2 Troubleshooting article as a baseline for resolving any SDK issues.

  Some important programming tips when using Direct mode:

  - **Use multithreading in your application for efficient TCP data transfer** - After making a request, your application should subscribe to receive data on another thread. Not doing so forces unintended "half-duplex" operation and the subsequent requests are blocked waiting for the previous request's reply.
  - **Carry out compute-intensive workloads on a dedicated thread** - For similar reasons to the previous tip, operations such as complex data processing are best placed in a separate thread. A request that pulls in data from another data store (for example if the thread utilizes Azure Cosmos DB and Spark data stores simultaneously) may experience increased latency and it is recommended to spawn an additional thread that awaits a response from the other data store.
    - The underlying network IO in the Azure Cosmos DB Async Java SDK v2 is managed by Netty, see these tips for avoiding coding patterns that block Netty IO threads.
  - **Data modeling** - The Azure Cosmos DB SLA assumes document size to be less than 1KB. Optimizing your data model and programming to favor smaller document size will generally lead to decreased latency. If you are going to need storage and retrieval of docs larger than 1KB, the recommended approach is for documents to link to data in Azure Blob Storage.

- **Tuning parallel queries for partitioned collections**

  Azure Cosmos DB Async Java SDK v2 supports parallel queries, which enable you to query a partitioned collection in parallel. For more information, see code samples related to working with the SDKs. Parallel queries are designed to improve query latency and throughput over their serial counterpart.

  - ***Tuning setMaxDegreeOfParallelism:***

    Parallel queries work by querying multiple partitions in parallel. However, data from an individual partitioned collection is fetched serially with respect to the query. So, use setMaxDegreeOfParallelism to set the number of partitions that has the maximum chance of achieving the most performant query, provided all other system conditions remain the same. If you don't know the number of partitions, you can use setMaxDegreeOfParallelism to set a high number,

and the system chooses the minimum (number of partitions, user provided input) as the maximum degree of parallelism.

It is important to note that parallel queries produce the best benefits if the data is evenly distributed across all partitions with respect to the query. If the partitioned collection is partitioned such a way that all or a majority of the data returned by a query is concentrated in a few partitions (one partition in worst case), then the performance of the query would be bottlenecked by those partitions.

- *Tuning setMaxBufferedItemCount:*

  Parallel query is designed to pre-fetch results while the current batch of results is being processed by the client. The pre-fetching helps in overall latency improvement of a query. setMaxBufferedItemCount limits the number of pre-fetched results. Setting setMaxBufferedItemCount to the expected number of results returned (or a higher number) enables the query to receive maximum benefit from pre-fetching.

  Pre-fetching works the same way irrespective of the MaxDegreeOfParallelism, and there is a single buffer for the data from all partitions.

- **Implement backoff at getRetryAfterInMilliseconds intervals**

  During performance testing, you should increase load until a small rate of requests get throttled. If throttled, the client application should backoff for the server-specified retry interval. Respecting the backoff ensures that you spend minimal amount of time waiting between retries.

- **Scale out your client-workload**

  If you are testing at high throughput levels (>50,000 RU/s), the client application may become the bottleneck due to the machine capping out on CPU or network utilization. If you reach this point, you can continue to push the Azure Cosmos DB account further by scaling out your client applications across multiple servers.

- **Use name based addressing**

  Use name-based addressing, where links have the format `dbs/MyDatabaseId/colls/MyCollectionId/docs/MyDocumentId`, instead of SelfLinks (_self), which have the format `dbs/<database_rid>/colls/<collection_rid>/docs/<document_rid>` to avoid retrieving ResourceIds of all the resources used to construct the link. Also, as these resources get recreated (possibly with same name), caching them may not help.

- **Tune the page size for queries/read feeds for better performance**

  When performing a bulk read of documents by using read feed functionality (for example, readDocuments) or when issuing a SQL query, the results are returned in a segmented fashion if the result set is too large. By default, results are returned in chunks of 100 items or 1 MB, whichever limit is hit first.

  To reduce the number of network round trips required to retrieve all applicable results, you can increase the page size using the x-ms-max-item-count request header to up to 1000. In cases where you need to display only a few results, for example, if your user interface or application API returns only 10 results a time, you can also decrease the page size to 10 to reduce the throughput consumed for reads and queries.

  You may also set the page size using the setMaxItemCount method.

- **Use Appropriate Scheduler (Avoid stealing Event loop IO Netty threads)**

  The Azure Cosmos DB Async Java SDK v2 uses netty for non-blocking IO. The SDK uses a fixed number of IO netty event loop threads (as many CPU cores your machine has) for executing IO operations. The Observable returned by API emits the result on one of the shared IO event loop netty threads. So it is

important to not block the shared IO event loop netty threads. Doing CPU intensive work or blocking operation on the IO event loop netty thread may cause deadlock or significantly reduce SDK throughput.

For example the following code executes a cpu intensive work on the event loop IO netty thread:

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
Observable<ResourceResponse<Document>> createDocObs = asyncDocumentClient.createDocument(
  collectionLink, document, null, true);

createDocObs.subscribe(
  resourceResponse -> {
    //this is executed on eventloop IO netty thread.
    //the eventloop thread is shared and is meant to return back quickly.
    //
    // DON'T do this on eventloop IO netty thread.
    veryCpuIntensiveWork();
  });
```

After result is received if you want to do CPU intensive work on the result you should avoid doing so on event loop IO netty thread. You can instead provide your own Scheduler to provide your own thread for running your work.

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
import rx.schedulers;

Observable<ResourceResponse<Document>> createDocObs = asyncDocumentClient.createDocument(
  collectionLink, document, null, true);

createDocObs.subscribeOn(Schedulers.computation())
subscribe(
  resourceResponse -> {
    // this is executed on threads provided by Scheduler.computation()
    // Schedulers.computation() should be used only when:
    //   1. The work is cpu intensive
    //   2. You are not doing blocking IO, thread sleep, etc. in this thread against other
resources.
    veryCpuIntensiveWork();
  });
```

Based on the type of your work you should use the appropriate existing RxJava Scheduler for your work. Read here `Schedulers`.

For More Information, Please look at the GitHub page for Azure Cosmos DB Async Java SDK v2.

- **Disable netty's logging**

  Netty library logging is chatty and needs to be turned off (suppressing sign in the configuration may not be enough) to avoid additional CPU costs. If you are not in debugging mode, disable netty's logging altogether. So if you are using log4j to remove the additional CPU costs incurred by `org.apache.log4j.Category.callAppenders()` from netty add the following line to your codebase:

```
org.apache.log4j.Logger.getLogger("io.netty").setLevel(org.apache.log4j.Level.OFF);
```

- **OS Open files Resource Limit**

  Some Linux systems (like Red Hat) have an upper limit on the number of open files and so the total number of connections. Run the following to view the current limits:

```
ulimit -a
```

The number of open files (nofile) needs to be large enough to have enough room for your configured connection pool size and other open files by the OS. It can be modified to allow for a larger connection pool size.

Open the limits.conf file:

```
vim /etc/security/limits.conf
```

Add/modify the following lines:

```
* - nofile 100000
```

Indexing Policy

- **Exclude unused paths from indexing for faster writes**

  Azure Cosmos DB's indexing policy allows you to specify which document paths to include or exclude from indexing by leveraging Indexing Paths (setIncludedPaths and setExcludedPaths). The use of indexing paths can offer improved write performance and lower index storage for scenarios in which the query patterns are known beforehand, as indexing costs are directly correlated to the number of unique paths indexed. For example, the following code shows how to exclude an entire section of the documents (also known as a subtree) from indexing using the "*" wildcard.

  Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
Index numberIndex = Index.Range(DataType.Number);
numberIndex.set("precision", -1);
indexes.add(numberIndex);
includedPath.setIndexes(indexes);
includedPaths.add(includedPath);
indexingPolicy.setIncludedPaths(includedPaths);
collectionDefinition.setIndexingPolicy(indexingPolicy);
```

  For more information, see Azure Cosmos DB indexing policies.

Throughput

- **Measure and tune for lower request units/second usage**

  Azure Cosmos DB offers a rich set of database operations including relational and hierarchical queries with UDFs, stored procedures, and triggers – all operating on the documents within a database collection. The cost associated with each of these operations varies based on the CPU, IO, and memory required to complete the operation. Instead of thinking about and managing hardware resources, you can think of a request unit (RU) as a single measure for the resources required to perform various database operations and service an application request.

  Throughput is provisioned based on the number of request units set for each container. Request unit consumption is evaluated as a rate per second. Applications that exceed the provisioned request unit rate for their container are limited until the rate drops below the provisioned level for the container. If your application requires a higher level of throughput, you can increase your throughput by provisioning additional request units.

The complexity of a query impacts how many request units are consumed for an operation. The number of predicates, nature of the predicates, number of UDFs, and the size of the source data set all influence the cost of query operations.

To measure the overhead of any operation (create, update, or delete), inspect the x-ms-request-charge header to measure the number of request units consumed by these operations. You can also look at the equivalent RequestCharge property in ResourceResponse<T> or FeedResponse<T>.

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
ResourceResponse<Document> response = asyncClient.createDocument(collectionLink, documentDefinition,
null,
                                                    false).toBlocking.single();
response.getRequestCharge();
```

The request charge returned in this header is a fraction of your provisioned throughput. For example, if you have 2000 RU/s provisioned, and if the preceding query returns 1000 1KB-documents, the cost of the operation is 1000. As such, within one second, the server honors only two such requests before rate limiting subsequent requests. For more information, see Request units and the request unit calculator.

- **Handle rate limiting/request rate too large**

  When a client attempts to exceed the reserved throughput for an account, there is no performance degradation at the server and no use of throughput capacity beyond the reserved level. The server will preemptively end the request with RequestRateTooLarge (HTTP status code 429) and return the x-ms-retry-after-ms header indicating the amount of time, in milliseconds, that the user must wait before reattempting the request.

  ```
  HTTP Status 429,
  Status Line: RequestRateTooLarge
  x-ms-retry-after-ms :100
  ```

  The SDKs all implicitly catch this response, respect the server-specified retry-after header, and retry the request. Unless your account is being accessed concurrently by multiple clients, the next retry will succeed.

  If you have more than one client cumulatively operating consistently above the request rate, the default retry count currently set to 9 internally by the client may not suffice; in this case, the client throws a DocumentClientException with status code 429 to the application. The default retry count can be changed by using setRetryOptions on the ConnectionPolicy instance. By default, the DocumentClientException with status code 429 is returned after a cumulative wait time of 30 seconds if the request continues to operate above the request rate. This occurs even when the current retry count is less than the max retry count, be it the default of 9 or a user-defined value.

  While the automated retry behavior helps to improve resiliency and usability for the most applications, it might come at odds when doing performance benchmarks, especially when measuring latency. The client-observed latency will spike if the experiment hits the server throttle and causes the client SDK to silently retry. To avoid latency spikes during performance experiments, measure the charge returned by each operation and ensure that requests are operating below the reserved request rate. For more information, see Request units.

- **Design for smaller documents for higher throughput**

  The request charge (the request processing cost) of a given operation is directly correlated to the size of the document. Operations on large documents cost more than operations for small documents.

Performance tips for Azure Cosmos DB Sync Java SDK v2

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> This is *not* the latest Java SDK for Azure Cosmos DB! You should upgrade your project to Azure Cosmos DB Java SDK v4 and then read the Azure Cosmos DB Java SDK v4 performance tips guide. Follow the instructions in the Migrate to Azure Cosmos DB Java SDK v4 guide and Reactor vs RxJava guide to upgrade.
>
> These performance tips are for Azure Cosmos DB Sync Java SDK v2 only. Please view the Azure Cosmos DB Sync Java SDK v2 Release notes and Maven repository for more information.

Azure Cosmos DB is a fast and flexible distributed database that scales seamlessly with guaranteed latency and throughput. You do not have to make major architecture changes or write complex code to scale your database with Azure Cosmos DB. Scaling up and down is as easy as making a single API call. To learn more, see how to provision container throughput or how to provision database throughput. However, because Azure Cosmos DB is accessed via network calls there are client-side optimizations you can make to achieve peak performance when using Azure Cosmos DB Sync Java SDK v2.

So if you're asking "How can I improve my database performance?" consider the following options:

Networking

1. **Connection mode: Use DirectHttps**

   How a client connects to Azure Cosmos DB has important implications on performance, especially in terms of observed client-side latency. There is one key configuration setting available for configuring the client ConnectionPolicy – the ConnectionMode. The two available ConnectionModes are:

   a. Gateway (default)

   b. DirectHttps

      Gateway mode is supported on all SDK platforms and is the configured default. If your application runs within a corporate network with strict firewall restrictions, Gateway is the best choice since it uses the standard HTTPS port and a single endpoint. The performance tradeoff, however, is that Gateway mode involves an additional network hop every time data is read or written to Azure Cosmos DB. Because of this, DirectHttps mode offers better performance due to fewer network hops.

      The Azure Cosmos DB Sync Java SDK v2 uses HTTPS as a transport protocol. HTTPS uses TLS for initial authentication and encrypting traffic. When using the Azure Cosmos DB Sync Java SDK v2, only HTTPS port 443 needs to be open.

      The ConnectionMode is configured during the construction of the DocumentClient instance with the ConnectionPolicy parameter.

   Sync Java SDK V2 (Maven com.microsoft.azure::azure-documentdb)

```
public ConnectionPolicy getConnectionPolicy() {
  ConnectionPolicy policy = new ConnectionPolicy();
  policy.setConnectionMode(ConnectionMode.DirectHttps);
  policy.setMaxPoolSize(1000);
  return policy;
}

ConnectionPolicy connectionPolicy = new ConnectionPolicy();
DocumentClient client = new DocumentClient(HOST, MASTER_KEY, connectionPolicy, null);
```

2. **Collocate clients in same Azure region for performance**

   When possible, place any applications calling Azure Cosmos DB in the same region as the Azure Cosmos database. For an approximate comparison, calls to Azure Cosmos DB within the same region complete within 1-2 ms, but the latency between the West and East coast of the US is >50 ms. This latency can likely vary from request to request depending on the route taken by the request as it passes from the client to the Azure datacenter boundary. The lowest possible latency is achieved by ensuring the calling application is located within the same Azure region as the provisioned Azure Cosmos DB endpoint. For a list of available regions, see Azure Regions.

SDK Usage

1. **Install the most recent SDK**

   The Azure Cosmos DB SDKs are constantly being improved to provide the best performance. See the Azure Cosmos DB SDK pages to determine the most recent SDK and review improvements.

2. **Use a singleton Azure Cosmos DB client for the lifetime of your application**

Each DocumentClient instance is thread-safe and performs efficient connection management and address caching when operating in Direct Mode. To allow efficient connection management and better performance by DocumentClient, it is recommended to use a single instance of DocumentClient per AppDomain for the lifetime of the application.

3. **Increase MaxPoolSize per host when using Gateway mode**

   Azure Cosmos DB requests are made over HTTPS/REST when using Gateway mode, and are subjected to the default connection limit per hostname or IP address. You may need to set the MaxPoolSize to a higher value (200-1000) so that the client library can utilize multiple simultaneous connections to Azure Cosmos DB. In the Azure Cosmos DB Sync Java SDK v2, the default value for ConnectionPolicy.getMaxPoolSize is 100. Use setMaxPoolSize to change the value.

4. **Tuning parallel queries for partitioned collections**

   Azure Cosmos DB Sync Java SDK version 1.9.0 and above support parallel queries, which enable you to query a partitioned collection in parallel. For more information, see code samples related to working with the SDKs. Parallel queries are designed to improve query latency and throughput over their serial counterpart.

   (a) ***Tuning setMaxDegreeOfParallelism:*** Parallel queries work by querying multiple partitions in parallel. However, data from an individual partitioned collection is fetched serially with respect to the query. So, use setMaxDegreeOfParallelism to set the number of partitions that has the maximum chance of achieving the most performant query, provided all other system conditions remain the same. If you don't know the number of partitions, you can use setMaxDegreeOfParallelism to set a high number, and the system chooses the minimum (number of partitions, user provided input) as the maximum degree of parallelism.

   It is important to note that parallel queries produce the best benefits if the data is evenly distributed across all partitions with respect to the query. If the partitioned collection is partitioned such a way that all or a majority of the data returned by a query is concentrated in a few partitions (one partition in worst case), then the performance of the query would be bottlenecked by those partitions.

   (b) ***Tuning setMaxBufferedItemCount:*** Parallel query is designed to pre-fetch results while the current batch of results is being processed by the client. The pre-fetching helps in overall latency improvement of a query. setMaxBufferedItemCount limits the number of pre-fetched results. By setting setMaxBufferedItemCount to the expected number of results returned (or a higher number), this enables the query to receive maximum benefit from pre-fetching.

   Pre-fetching works the same way irrespective of the MaxDegreeOfParallelism, and there is a single buffer for the data from all partitions.

5. **Implement backoff at getRetryAfterInMilliseconds intervals**

   During performance testing, you should increase load until a small rate of requests get throttled. If throttled, the client application should backoff on throttle for the server-specified retry interval. Respecting the backoff ensures that you spend minimal amount of time waiting between retries. Retry policy support is included in Version 1.8.0 and above of the Azure Cosmos DB Sync Java SDK. For more information, see getRetryAfterInMilliseconds.

6. **Scale out your client-workload**

   If you are testing at high throughput levels (>50,000 RU/s), the client application may become the bottleneck due to the machine capping out on CPU or network utilization. If you reach this point, you can continue to push the Azure Cosmos DB account further by scaling out your client applications across multiple servers.

7. **Use name based addressing**

Use name-based addressing, where links have the format `dbs/MyDatabaseId/colls/MyCollectionId/docs/MyDocumentId`, instead of SelfLinks (_self), which have the format `dbs/<database_rid>/colls/<collection_rid>/docs/<document_rid>` to avoid retrieving ResourceIds of all the resources used to construct the link. Also, as these resources get recreated (possibly with same name), caching these may not help.

8. **Tune the page size for queries/read feeds for better performance**

   When performing a bulk read of documents by using read feed functionality (for example, readDocuments) or when issuing a SQL query, the results are returned in a segmented fashion if the result set is too large. By default, results are returned in chunks of 100 items or 1 MB, whichever limit is hit first.

   To reduce the number of network round trips required to retrieve all applicable results, you can increase the page size using the x-ms-max-item-count request header to up to 1000. In cases where you need to display only a few results, for example, if your user interface or application API returns only 10 results a time, you can also decrease the page size to 10 to reduce the throughput consumed for reads and queries.

   You may also set the page size using the setPageSize method.

Indexing Policy

1. **Exclude unused paths from indexing for faster writes**

   Azure Cosmos DB's indexing policy allows you to specify which document paths to include or exclude from indexing by leveraging Indexing Paths (setIncludedPaths and setExcludedPaths). The use of indexing paths can offer improved write performance and lower index storage for scenarios in which the query patterns are known beforehand, as indexing costs are directly correlated to the number of unique paths indexed. For example, the following code shows how to exclude an entire section (subtree) of the documents from indexing using the "*" wildcard.

   Sync Java SDK V2 (Maven com.microsoft.azure::azure-documentdb)

   ```
   Index numberIndex = Index.Range(DataType.Number);
   numberIndex.set("precision", -1);
   indexes.add(numberIndex);
   includedPath.setIndexes(indexes);
   includedPaths.add(includedPath);
   indexingPolicy.setIncludedPaths(includedPaths);
   collectionDefinition.setIndexingPolicy(indexingPolicy);
   ```

   For more information, see Azure Cosmos DB indexing policies.

Throughput

1. **Measure and tune for lower request units/second usage**

   Azure Cosmos DB offers a rich set of database operations including relational and hierarchical queries with UDFs, stored procedures, and triggers – all operating on the documents within a database collection. The cost associated with each of these operations varies based on the CPU, IO, and memory required to complete the operation. Instead of thinking about and managing hardware resources, you can think of a request unit (RU) as a single measure for the resources required to perform various database operations and service an application request.

   Throughput is provisioned based on the number of request units set for each container. Request unit consumption is evaluated as a rate per second. Applications that exceed the provisioned request unit rate for their container are limited until the rate drops below the provisioned level for the container. If your application requires a higher level of throughput, you can increase your throughput by provisioning

additional request units.

The complexity of a query impacts how many request units are consumed for an operation. The number of predicates, nature of the predicates, number of UDFs, and the size of the source data set all influence the cost of query operations.

To measure the overhead of any operation (create, update, or delete), inspect the x-ms-request-charge header (or the equivalent RequestCharge property in ResourceResponse<T> or FeedResponse<T> to measure the number of request units consumed by these operations.

Sync Java SDK V2 (Maven com.microsoft.azure::azure-documentdb)

```
ResourceResponse<Document> response = client.createDocument(collectionLink, documentDefinition, null,
false);

response.getRequestCharge();
```

The request charge returned in this header is a fraction of your provisioned throughput. For example, if you have 2000 RU/s provisioned, and if the preceding query returns 1000 1KB-documents, the cost of the operation is 1000. As such, within one second, the server honors only two such requests before rate limiting subsequent requests. For more information, see Request units and the request unit calculator.

2. **Handle rate limiting/request rate too large**

   When a client attempts to exceed the reserved throughput for an account, there is no performance degradation at the server and no use of throughput capacity beyond the reserved level. The server will preemptively end the request with RequestRateTooLarge (HTTP status code 429) and return the x-ms-retry-after-ms header indicating the amount of time, in milliseconds, that the user must wait before reattempting the request.

```
HTTP Status 429,
Status Line: RequestRateTooLarge
x-ms-retry-after-ms :100
```

   The SDKs all implicitly catch this response, respect the server-specified retry-after header, and retry the request. Unless your account is being accessed concurrently by multiple clients, the next retry will succeed.

   If you have more than one client cumulatively operating consistently above the request rate, the default retry count currently set to 9 internally by the client may not suffice; in this case, the client throws a DocumentClientException with status code 429 to the application. The default retry count can be changed by using setRetryOptions on the ConnectionPolicy instance. By default, the DocumentClientException with status code 429 is returned after a cumulative wait time of 30 seconds if the request continues to operate above the request rate. This occurs even when the current retry count is less than the max retry count, be it the default of 9 or a user-defined value.

   While the automated retry behavior helps to improve resiliency and usability for the most applications, it might come at odds when doing performance benchmarks, especially when measuring latency. The client-observed latency will spike if the experiment hits the server throttle and causes the client SDK to silently retry. To avoid latency spikes during performance experiments, measure the charge returned by each operation and ensure that requests are operating below the reserved request rate. For more information, see Request units.

3. **Design for smaller documents for higher throughput**

   The request charge (the request processing cost) of a given operation is directly correlated to the size of the document. Operations on large documents cost more than operations for small documents.

Performance and scale testing with Azure Cosmos DB

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

Performance and scale testing is a key step in application development. For many applications, the database tier has a significant impact on overall performance and scalability. Therefore, it's a critical component of performance testing. Azure Cosmos DB is purpose-built for elastic scale and predictable performance. These capabilities make it a great fit for applications that need a high-performance database tier.

This article is a reference for developers implementing performance test suites for their Azure Cosmos DB workloads. It also can be used to evaluate Azure Cosmos DB for high-performance application scenarios. It focuses primarily on isolated performance testing of the database, but also includes best practices for production applications.

After reading this article, you'll be able to answer the following questions:

- Where can I find a sample .NET client application for performance testing of Azure Cosmos DB?
- How do I achieve high throughput levels with Azure Cosmos DB from my client application?

To get started with code, download the project from Azure Cosmos DB performance testing sample.

> **NOTE**
> The goal of this application is to demonstrate how to get the best performance from Azure Cosmos DB with a small number of client machines. The goal of the sample is not to achieve the peak throughput capacity of Azure Cosmos DB (which can scale without any limits).

If you're looking for client-side configuration options to improve Azure Cosmos DB performance, see Azure Cosmos DB performance tips.

Run the performance testing application

The quickest way to get started is to compile and run the .NET sample, as described in the following steps. You can also review the source code and implement similar configurations on your own client applications.

Step 1: Download the project from Azure Cosmos DB performance testing sample, or fork the GitHub repository.

Step 2: Modify the settings for EndpointUrl, AuthorizationKey, CollectionThroughput, and DocumentTemplate (optional) in App.config.

> **NOTE**
> Before you provision collections with high throughput, refer to the Pricing page to estimate the costs per collection. Azure Cosmos DB bills storage and throughput independently on an hourly basis. You can save costs by deleting or lowering the throughput of your Azure Cosmos containers after testing.

Step 3: Compile and run the console app from the command line. You should see output like the following:

```
C:\Users\cosmosdb\Desktop\Benchmark>DocumentDBBenchmark.exe
Summary:
---------------------------------------------------------------------
Endpoint: https://arramacquerymetrics.documents.azure.com:443/
Collection : db.data at 100000 request units per second
Document Template*: Player.json
Degree of parallelism*: -1
---------------------------------------------------------------------
DocumentDBBenchmark starting...
Found collection data with 100000 RU/s
Starting Inserts with 100 tasks
Inserted 4503 docs @ 4491 writes/s, 47070 RU/s (122B max monthly 1KB reads)
Inserted 17910 docs @ 8862 writes/s, 92878 RU/s (241B max monthly 1KB reads)
Inserted 32339 docs @ 10531 writes/s, 110366 RU/s (286B max monthly 1KB reads)
Inserted 47848 docs @ 11675 writes/s, 122357 RU/s (317B max monthly 1KB reads)
Inserted 58857 docs @ 11545 writes/s, 120992 RU/s (314B max monthly 1KB reads)
Inserted 69547 docs @ 11378 writes/s, 119237 RU/s (309B max monthly 1KB reads)
Inserted 80687 docs @ 11345 writes/s, 118896 RU/s (308B max monthly 1KB reads)
Inserted 91455 docs @ 11272 writes/s, 118131 RU/s (306B max monthly 1KB reads)
Inserted 102129 docs @ 11208 writes/s, 117461 RU/s (304B max monthly 1KB reads)
Inserted 112444 docs @ 11120 writes/s, 116538 RU/s (302B max monthly 1KB reads)
Inserted 122927 docs @ 11063 writes/s, 115936 RU/s (301B max monthly 1KB reads)
Inserted 133157 docs @ 10993 writes/s, 115208 RU/s (299B max monthly 1KB reads)
Inserted 144078 docs @ 10988 writes/s, 115159 RU/s (298B max monthly 1KB reads)
Inserted 155415 docs @ 11013 writes/s, 115415 RU/s (299B max monthly 1KB reads)
Inserted 166126 docs @ 10992 writes/s, 115198 RU/s (299B max monthly 1KB reads)
Inserted 173051 docs @ 10739 writes/s, 112544 RU/s (292B max monthly 1KB reads)
Inserted 180169 docs @ 10527 writes/s, 110324 RU/s (286B max monthly 1KB reads)
Inserted 192469 docs @ 10616 writes/s, 111256 RU/s (288B max monthly 1KB reads)
Inserted 199107 docs @ 10406 writes/s, 109054 RU/s (283B max monthly 1KB reads)
Inserted 200000 docs @ 9930 writes/s, 104065 RU/s (270B max monthly 1KB reads)

Summary:
---------------------------------------------------------------------
Inserted 200000 docs @ 9928 writes/s, 104063 RU/s (270B max monthly 1KB reads)
---------------------------------------------------------------------
DocumentDBBenchmark completed successfully.

```

Step 4 (if necessary): The throughput reported (RU/s) from the tool should be the same or higher than the provisioned throughput of the collection or a set of collections. If it's not, increasing the DegreeOfParallelism in small increments might help you reach the limit. If the throughput from your client app plateaus, start multiple instances of the app on additional client machines. If you need help with this step file a support ticket from the Azure portal.

After you have the app running, you can try different indexing policies and consistency levels to understand their impact on throughput and latency. You can also review the source code and implement similar configurations to your own test suites or production applications.

Next steps

In this article, we looked at how you can perform performance and scale testing with Azure Cosmos DB by using a .NET console app. For more information, see the following articles:

- Azure Cosmos DB performance testing sample
- Client configuration options to improve Azure Cosmos DB performance
- Server-side partitioning in Azure Cosmos DB

Azure Cosmos DB as a key value store – cost overview

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is a globally distributed, multi-model database service for building highly available, large-scale applications easily. By default, Azure Cosmos DB automatically and efficiently indexes all the data it ingests. This enables fast and consistent SQL (and JavaScript) queries on the data.

This article describes the cost of Azure Cosmos DB for simple write and read operations when it's used as a key/value store. Write operations include inserts, replaces, deletes, and upserts of data items. Besides guaranteeing a 99.999% availability SLA for all multi-region accounts, Azure Cosmos DB offers guaranteed <10-ms latency for reads and for the (indexed) writes, at the 99th percentile.

Why we use Request Units (RUs)

Azure Cosmos DB performance is based on the amount of provisioned throughput expressed in Request Units (RU/s). The provisioning is at a second granularity and is purchased in RU/s (not to be confused with the hourly billing). RUs should be considered as a logical abstraction (a currency) that simplifies the provisioning of required throughput for the application. Users do not have to think of differentiating between read and write throughput. The single currency model of RUs creates efficiencies to share the provisioned capacity between reads and writes. This provisioned capacity model enables the service to provide a **predictable and consistent throughput, guaranteed low latency, and high availability**. Finally, while RU model is used to depict throughput, each provisioned RU also has a defined amount of resources (e.g., memory, cores/CPU and IOPS).

As a globally distributed database system, Cosmos DB is the only Azure service that provides comprehensive SLAs covering latency, throughput, consistency and high availability. The throughput you provision is applied to each of the regions associated with your Cosmos account. For reads, Cosmos DB offers multiple, well-defined consistency levels for you to choose from.

The following table shows the number of RUs required to perform read and write operations based on a data item of size 1 KB and 100 KBs with default automatic indexing turned off.

ITEM SIZE	1 READ	1 WRITE
1 KB	1 RU	5 RUs
100 KB	10 RUs	50 RUs

Cost of reads and writes

If you provision 1,000 RU/s, this amounts to 3.6 million RU/hour and will cost $0.08 for the hour (in the US and Europe). For a 1 KB size data item, this means that you can consume 3.6 million reads or 0.72 million writes (3.6 million RU / 5) using your provisioned throughput. Normalized to million reads and writes, the cost would be $0.022 /million of reads ($0.08 / 3.6) and $0.111/million of writes ($0.08 / 0.72). The cost per million becomes minimal as shown in the table below.

ITEM SIZE	COST OF 1 MILLION READS	COST OF 1 MILLION WRITES
1 KB	$0.022	$0.111
100 KB	$0.222	$1.111

Most of the basic blob or object stores services charge $0.40 per million read transaction and $5 per million write transaction. If used optimally, Cosmos DB can be up to 98% cheaper than these other solutions (for 1 KB transactions).

Next steps

- Use RU calculator to estimate throughput for your workloads.

Migrate your application to use the Azure Cosmos DB Java SDK v4

12/4/2020 • 10 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> For more information about this SDK, please view the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, Azure Cosmos DB Java SDK v4 performance tips, and Azure Cosmos DB Java SDK v4 troubleshooting guide.

This article explains how to upgrade your existing Java application that is using an older Azure Cosmos DB Java SDK to the newer Azure Cosmos DB Java SDK 4.0 for Core (SQL) API. Azure Cosmos DB Java SDK v4 corresponds to the `com.azure.cosmos` package. You can use the instructions in this doc if you are migrating your application from any of the following Azure Cosmos DB Java SDKs:

- Sync Java SDK 2.x.x
- Async Java SDK 2.x.x
- Java SDK 3.x.x

Azure Cosmos DB Java SDK's and package mappings

The following table lists different Azure Cosmos DB Java SDKs, the package name and the release information:

JAVA SDK	RELEASE DATE	BUNDLED APIS	MAVEN JAR	JAVA PACKAGE NAME	API REFERENCE	RELEASE NOTES
Async 2.x.x	June 2018	Async(RxJava)	`com.microsoft.az` `cosmosdb`	`com.microsoft.azure.cosmosdb.rx`	API	Release Notes
Sync 2.x.x	Sept 2018	Sync	`com.microsoft.az` `documentdb`	`com.microsoft.azure.cosmosdb`	API	Release Notes
3.x.x	July 2019	Async(Reactor)/Sync	`com.microsoft.az` `cosmos`	`com.azure.data.cosmos`	API	-
4.0	June 2020	Async(Reactor)/Sync	`com.azure::azure` `cosmos`	`com.azure.cosmos`	API	API

SDK level implementation changes

The following are the key implementation differences between different SDKs:

RxJava is replaced with reactor in Azure Cosmos DB Java SDK versions 3.x.x and 4.0

If you are unfamiliar with asynchronous programming or Reactive Programming, see the Reactor pattern guide for an introduction to async programming and Project Reactor. This guide may be useful if you have been using Azure Cosmos DB Sync Java SDK 2.x.x or Azure Cosmos DB Java SDK 3.x.x Sync API in the past.

If you have been using Azure Cosmos DB Async Java SDK 2.x.x, and you plan on migrating to the 4.0 SDK, see the

Reactor vs RxJava Guide for guidance on converting RxJava code to use Reactor.

Azure Cosmos DB Java SDK v4 has direct connectivity mode in both Async and Sync APIs

If you have been using Azure Cosmos DB Sync Java SDK 2.x.x, note that the direct connection mode based on TCP (as opposed to HTTP) is implemented in Azure Cosmos DB Java SDK 4.0 for both the Async and Sync APIs.

API level changes

The following are the API level changes in Azure Cosmos DB Java SDK 4.x.x compared to previous SDKs (Java SDK 3.x.x, Async Java SDK 2.x.x, and Sync Java SDK 2.x.x):

- **Java SDK 3.x.x and 4.x.x**

Java SDK Version	Sync API	Async API
Java SDK 4.0	CosmosClient	CosmosAsyncClient
Java SDK 3.x.x	CosmosSyncClient	CosmosClient

- **Async Java SDK 2.x.x and "Legacy" Sync Java SDK 2.x.x**

Java SDK Version	Class Name
Async Java SDK 2.x.x	AsyncDocumentClient
"Legacy" Sync Java SDK 2.x.x	DocumentClient

- The Azure Cosmos DB Java SDK 3.x.x and 4.0 refer the client resources as `Cosmos<resourceName>`. For example, `CosmosClient`, `CosmosDatabase`, `CosmosContainer`. Whereas in version 2.x.x, the Azure Cosmos DB Java SDKs don't have a uniform naming scheme.
- Azure Cosmos DB Java SDK 3.x.x and 4.0 offer both Sync and Async APIs.
  - **Java SDK 4.0** : All the classes belong to the Sync API unless the class name is appended with `Async` after `Cosmos`.
  - **Java SDK 3.x.x**: All the classes belong to the Async API unless the class name is appended with `Async` after `Cosmos`.
  - **Async Java SDK 2.x.x**: The class names are similar to Sync Java SDK 2.x.x, however the name starts with *Async*.

Hierarchical API structure

Azure Cosmos DB Java SDK 4.0 and 3.x.x introduce a hierarchical API structure that organizes the clients, databases, and containers in a nested fashion as shown in the following 4.0 SDK code snippet:

```
CosmosContainer container = client.getDatabase("MyDatabaseName").getContainer("MyContainerName");
```

In version 2.x.x of the Azure Cosmos DB Java SDK, all operations on resources and documents are performed through the client instance.

Representing documents

In Azure Cosmos DB Java SDK 4.0, custom POJO's and `JsonNodes` are the two options to read and write the documents from Azure Cosmos DB.

In the Azure Cosmos DB Java SDK 3.x.x, the `CosmosItemProperties` object is exposed by the public API and served as a document representation. This class is no longer exposed publicly in version 4.0.

Imports

- The Azure Cosmos DB Java SDK 4.0 packages begin with `com.azure.cosmos`
  - Azure Cosmos DB Java SDK 3.x.x packages begin with `com.azure.data.cosmos`
- Azure Cosmos DB Java SDK 4.0 places several classes in a nested package `com.azure.cosmos.models`. Some of these packages include:
  - `CosmosContainerResponse`
  - `CosmosDatabaseResponse`
  - `CosmosItemResponse`
  - The Async API analogs for all of the above packages
  - `CosmosContainerProperties`
  - `FeedOptions`
  - `PartitionKey`
  - `IndexingPolicy`
  - `IndexingMode` ...etc.

Accessors

Azure Cosmos DB Java SDK 4.0 exposes `get` and `set` methods to access the instance members. For example, the `CosmosContainer` instance has `container.getId()` and `container.setId()` methods.

This is different from Azure Cosmos DB Java SDK 3.x.x which exposes a fluent interface. For example, a `CosmosSyncContainer` instance has `container.id()` which is overloaded to get or set the `id` value.

Code snippet comparisons

Create resources

The following code snippet shows the differences in how resources are created between the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
// Create Async client.
// Building an async client is still a sync operation.
CosmosAsyncClient client = new CosmosClientBuilder()
        .endpoint("your.hostname")
        .key("yourmasterkey")
        .consistencyLevel(ConsistencyLevel.EVENTUAL)
        .buildAsyncClient();

// Create database with specified name
client.createDatabaseIfNotExists("YourDatabaseName")
        .flatMap(databaseResponse -> {
            testDatabaseAsync = client.getDatabase("YourDatabaseName");
            // Container properties - name and partition key
            CosmosContainerProperties containerProperties =
                    new CosmosContainerProperties("YourContainerName", "/id");

            // Provision manual throughput
            ThroughputProperties throughputProperties = ThroughputProperties.createManualThroughput(400);

            // Create container
            return database.createContainerIfNotExists(containerProperties, throughputProperties);
        }).flatMap(containerResponse -> {
    testContainerAsync = database.getContainer("YourContainerName");
    return Mono.empty();
}).subscribe();
```

Item operations

The following code snippet shows the differences in how item operations are performed between the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
// Container is created. Generate many docs to insert.
int number_of_docs = 50000;
ArrayList<JsonNode> docs = generateManyDocs(number_of_docs);

// Insert many docs into container...
Flux.fromIterable(docs)
        .flatMap(doc -> testContainerAsync.createItem(doc))
        .subscribe(); // ...Subscribing triggers stream execution.
```

Indexing

The following code snippet shows the differences in how indexing is created between the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
CosmosContainerProperties containerProperties = new CosmosContainerProperties(containerName, "/lastName");

// Custom indexing policy
IndexingPolicy indexingPolicy = new IndexingPolicy();
indexingPolicy.setIndexingMode(IndexingMode.CONSISTENT);

// Included paths
List<IncludedPath> includedPaths = new ArrayList<>();
includedPaths.add(new IncludedPath("/*"));
indexingPolicy.setIncludedPaths(includedPaths);

// Excluded paths
List<ExcludedPath> excludedPaths = new ArrayList<>();
excludedPaths.add(new ExcludedPath("/name/*"));
indexingPolicy.setExcludedPaths(excludedPaths);

containerProperties.setIndexingPolicy(indexingPolicy);

ThroughputProperties throughputProperties = ThroughputProperties.createManualThroughput(400);

database.createContainerIfNotExists(containerProperties, throughputProperties);
CosmosAsyncContainer containerIfNotExists = database.getContainer(containerName);
```

Stored procedures

The following code snippet shows the differences in how stored procedures are created between the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
logger.info("Creating stored procedure...\n");

String sprocId = "createMyDocument";

String sprocBody = "function createMyDocument() {\n" +
        "var documentToCreate = {\"id\":\"test_doc\"}\n" +
        "var context = getContext();\n" +
        "var collection = context.getCollection();\n" +
        "var accepted = collection.createDocument(collection.getSelfLink(), documentToCreate,\n" +
        "    function (err, documentCreated) {\n" +
        "if (err) throw new Error('Error' + err.message);\n" +
        "context.getResponse().setBody(documentCreated.id)\n" +
        "});\n" +
        "if (!accepted) return;\n" +
        "}";

CosmosStoredProcedureProperties storedProcedureDef = new CosmosStoredProcedureProperties(sprocId,
sprocBody);
container.getScripts()
        .createStoredProcedure(storedProcedureDef,
                new CosmosStoredProcedureRequestOptions()).block();

// ...

logger.info(String.format("Executing stored procedure %s...\n\n", sprocId));

CosmosStoredProcedureRequestOptions options = new CosmosStoredProcedureRequestOptions();
options.setPartitionKey(new PartitionKey("test_doc"));

container.getScripts()
        .getStoredProcedure(sprocId)
        .execute(null, options)
        .flatMap(executeResponse -> {
            logger.info(String.format("Stored procedure %s returned %s (HTTP %d), at cost %.3f RU.\n",
                    sprocId,
                    executeResponse.getResponseAsString(),
                    executeResponse.getStatusCode(),
                    executeResponse.getRequestCharge()));
            return Mono.empty();
        }).block();
```

Change feed

The following code snippet shows the differences in how change feed operations are executed between the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
ChangeFeedProcessor changeFeedProcessorInstance =
        new ChangeFeedProcessorBuilder()
                .hostName(hostName)
                .feedContainer(feedContainer)
                .leaseContainer(leaseContainer)
                .handleChanges((List<JsonNode> docs) -> {
                    logger.info("--->setHandleChanges() START");

                    for (JsonNode document : docs) {
                        try {
                            //Change Feed hands the document to you in the form of a JsonNode
                            //As a developer you have two options for handling the JsonNode document
provided to you by Change Feed
                            //One option is to operate on the document in the form of a JsonNode, as shown
below. This is great
                            //especially if you do not have a single uniform data model for all documents.
                            logger.info("---->DOCUMENT RECEIVED: " +
OBJECT_MAPPER.writerWithDefaultPrettyPrinter()
                                    .writeValueAsString(document));

                            //You can also transform the JsonNode to a POJO having the same structure as the
JsonNode,
                            //as shown below. Then you can operate on the POJO.
                            CustomPOJO pojo_doc = OBJECT_MAPPER.treeToValue(document, CustomPOJO.class);
                            logger.info("---->id: " + pojo_doc.getId());

                        } catch (JsonProcessingException e) {
                            e.printStackTrace();
                        }
                    }
                    logger.info("--->handleChanges() END");

                })
                .buildChangeFeedProcessor();

// ...

changeFeedProcessorInstance.start()
        .subscribeOn(Schedulers.elastic())
        .subscribe();
```

Container level Time-To-Live(TTL)

The following code snippet shows the differences in how to create time to live for data in the container using the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
CosmosAsyncContainer container;

// Create a new container with TTL enabled with default expiration value
CosmosContainerProperties containerProperties = new CosmosContainerProperties("myContainer",
"/myPartitionKey");
containerProperties.setDefaultTimeToLiveInSeconds(90 * 60 * 60 * 24);
ThroughputProperties throughputProperties = ThroughputProperties.createManualThroughput(400);
database.createContainerIfNotExists(containerProperties, throughputProperties).block();
container = database.getContainer("myContainer");
```

Item level Time-To-Live(TTL)

The following code snippet shows the differences in how to create time to live for an item using the 4.0 and 3.x.x Async APIs:

- Java SDK 4.0 Async API
- Java SDK 3.x.x Async API

```
// Include a property that serializes to "ttl" in JSON
class SalesOrder
{
    private String id;
    private String customerId;
    private Integer ttl;

    public SalesOrder(String id, String customerId, Integer ttl) {
        this.id = id;
        this.customerId = customerId;
        this.ttl = ttl;
    }

    public String getId() {return this.id;}
    public void setId(String new_id) {this.id = new_id;}
    public String getCustomerId() {return this.customerId;}
    public void setCustomerId(String new_cid) {this.customerId = new_cid;}
    public Integer getTtl() {return this.ttl;}
    public void setTtl(Integer new_ttl) {this.ttl = new_ttl;}

    //...
}
```

```
// Set the value to the expiration in seconds
SalesOrder salesOrder = new SalesOrder(
        "SO05",
        "CO18009186470",
        60 * 60 * 24 * 30  // Expire sales orders in 30 days
);
```

Migrate your application to use the Azure Cosmos DB .NET SDK v3

12/4/2020 • 11 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> To learn about the Azure Cosmos DB .NET SDK v3, see the Release notes, the .NET GitHub repository, .NET SDK v3 Performance Tips, and the Troubleshooting guide.

This article highlights some of the considerations of upgrading your existing .NET application to the newer Azure Cosmos DB .NET SDK v3 for Core (SQL) API. Azure Cosmos DB .NET SDK v3 corresponds to the Microsoft.Azure.Cosmos namespace. You can use the information provided in this doc if you are migrating your application from any of the following Azure Cosmos DB .NET SDKs:

- Azure Cosmos DB .NET Framework SDK v2 for SQL API
- Azure Cosmos DB .NET Core SDK v2 for SQL API

The instructions in this article also help you to migrate the following external libraries that are now part of the Azure Cosmos DB .NET SDK v3 for Core (SQL) API:

- .NET change feed processor library 2.0
- .NET bulk executor library 1.1 or greater

What's new in the .NET V3 SDK

The v3 SDK contains many usability and performance improvements, including:

- Intuitive programming model naming
- .NET Standard 2.0 **
- Increased performance through stream API support
- Fluent hierarchy that replaces the need for URI factory
- Built-in support for change feed processor library
- Built-in support for bulk operations
- Mockabale APIs for easier unit testing
- Transactional batch and Blazor support
- Pluggable serializers
- Scale non-partitioned and autoscale containers

** The SDK targets .NET Standard 2.0 that unifies the existing Azure Cosmos DB .NET Framework and .NET Core SDKs into a single .NET SDK. You can use the .NET SDK in any platform that implements .NET Standard 2.0, including your .NET Framework 4.6.1+ and .NET Core 2.0+ applications.

Most of the networking, retry logic, and lower levels of the SDK remain largely unchanged.

The Azure Cosmos DB .NET SDK v3 is now open source. We welcome any pull requests and will be logging issues and tracking feedback on GitHub. We'll work on taking on any features that will improve customer experience.

Why migrate to the .NET v3 SDK

In addition to the numerous usability and performance improvements, new feature investments made in the latest SDK will not be back ported to older versions.

While there are no immediate plans to retire support for the 2.0 SDKs, the SDKs will be replaced by newer versions in the future and the SDK will go into maintenance mode. For the best development experience, we recommend always starting with the latest supported version of SDK.

Major name changes from v2 SDK to v3 SDK

The following name changes have been applied throughout the .NET 3.0 SDK to align with the API naming conventions for the Core (SQL) API:

- `DocumentClient` is renamed to `CosmosClient`
- `Collection` is renamed to `Container`
- `Document` is renamed to `Item`

All the resource objects are renamed with additional properties, which, includes the resource name for clarity.

The following are some of the main class name changes:

.NET V2 SDK	.NET V3 SDK
`Microsoft.Azure.Documents.Client.DocumentClient`	`Microsoft.Azure.CosmosClient`
`Microsoft.Azure.Documents.Client.ConnectionPolicy`	`Microsoft.Azure.Cosmos.CosmosClientOptions`
`Microsoft.Azure.Documents.Client.DocumentClientException`	`Microsoft.Azure.Cosmos.CosmosException`
`Microsoft.Azure.Documents.Client.Database`	`Microsoft.Azure.Cosmos.DatabaseProperties`
`Microsoft.Azure.Documents.Client.DocumentCollection`	`Microsoft.Azure.Cosmos.ContainerProperties`
`Microsoft.Azure.Documents.Client.RequestOptions`	`Microsoft.Azure.Cosmos.ItemRequestOptions`
`Microsoft.Azure.Documents.Client.FeedOptions`	`Microsoft.Azure.Cosmos.QueryRequestOptions`
`Microsoft.Azure.Documents.Client.StoredProcedure`	`Microsoft.Azure.Cosmos.StoredProcedureProperties`
`Microsoft.Azure.Documents.Client.Trigger`	`Microsoft.Azure.Cosmos.TriggerProperties`

Classes replaced on .NET v3 SDK

The following classes have been replaced on the 3.0 SDK:

- `Microsoft.Azure.Documents.UriFactory`
- `Microsoft.Azure.Documents.Document`
- `Microsoft.Azure.Documents.Resource`

The Microsoft.Azure.Documents.UriFactory class has been replaced by the fluent design. The fluent design builds URLs internally and allows a single `Container` object to be passed around instead of a `DocumentClient`, `DatabaseName`, and `DocumentCollection`.

Changes to item ID generation

Item ID is no longer auto populated in the .NET v3 SDK. Therefore, the Item ID must specifically include a generated ID. View the following example:

```
[JsonProperty(PropertyName = "id")]
public Guid Id { get; set; }
```

Changed default behavior for connection mode

The SDK v3 now defaults to Direct + TCP connection modes compared to the previous v2 SDK, which defaulted to Gateway + HTTPS connections modes. This change provides enhanced performance and scalability.

Changes to FeedOptions (QueryRequestOptions in v3.0 SDK)

The `FeedOptions` class in SDK v2 has now been renamed to `QueryRequestOptions` in the SDK v3 and within the class, several properties have had changes in name and/or default value or been removed completely.

`FeedOptions.MaxDegreeOfParallelism` has been renamed to `QueryRequestOptions.MaxConcurrency` and default value and associated behavior remains the same, operations run client side during parallel query executionwill be executed serially with no-parallelism.

`FeedOptions.EnableCrossPartitionQuery` has been removed and the default behavior in SDK 3.0 is that cross-partition queries will be executed without the need to enable the property specifically.

`FeedOptions.PopulateQueryMetrics` is enabled by default with the results being present in the diagnostics property of the response.

`FeedOptions.RequestContinuation` has now been promoted to the query methods themselves.

The following properties have been removed:

- `FeedOptions.DisableRUPerMinuteUsage`
- `FeedOptions.EnableCrossPartitionQuery`
- `FeedOptions.JsonSerializerSettings`
- `FeedOptions.PartitionKeyRangeId`
- `FeedOptions.PopulateQueryMetrics`

Constructing a client

The .NET SDK v3 provides a fluent `CosmosClientBuilder` class that replaces the need for the SDK v2 URI Factory.

The following example creates a new `CosmosClientBuilder` with a strong ConsistencyLevel and a list of preferred locations:

```
CosmosClientBuilder cosmosClientBuilder = new CosmosClientBuilder(
    accountEndpoint: "https://testcosmos.documents.azure.com:443/",
    authKeyOrResourceToken: "SuperSecretKey")
.WithConsistencyLevel(ConsistencyLevel.Strong)
.WithApplicationRegion(Regions.EastUS);
CosmosClient client = cosmosClientBuilder.Build();
```

Using the change feed processor APIs directly from the v3 SDK

The v3 SDK has built-in support for the Change Feed Processor APIs, allowing you use the same SDK for building your application and change feed processor implementation. Previously, you had to use a separate change feed processor library.

For more information, see how to migrate from the change feed processor library to the Azure Cosmos DB .NET v3 SDK

Using the bulk executor library directly from the V3 SDK

The v3 SDK has built-in support for the bulk executor library, allowing you to use the same SDK for building your application and performing bulk operations. Previously, you were required to use a separate bulk executor library.

For more information, see how to migrate from the bulk executor library to bulk support in Azure Cosmos DB .NET V3 SDK

Code snippet comparisons

The following code snippet shows the differences in how resources are created between the .NET v2 and v3 SDKs:

Database operations

Create a database

- .NET SDK v3
- .NET SDK v2

```
// Create database with no shared provisioned throughput
DatabaseResponse databaseResponse = await client.CreateDatabaseIfNotExistsAsync(DatabaseName);
Database database = databaseResponse;
DatabaseProperties databaseProperties = databaseResponse;

// Create a database with a shared manual provisioned throughput
string databaseIdManual = new string(DatabaseName + "_SharedManualThroughput");
database = await client.CreateDatabaseIfNotExistsAsync(databaseIdManual,
ThroughputProperties.CreateManualThroughput(400));

// Create a database with shared autoscale provisioned throughput
string databaseIdAutoscale = new string(DatabaseName + "_SharedAutoscaleThroughput");
database = await client.CreateDatabaseIfNotExistsAsync(databaseIdAutoscale,
ThroughputProperties.CreateAutoscaleThroughput(4000));
```

Read a database by ID

- .NET SDK v3
- .NET SDK v2

```
// Read a database
Console.WriteLine($"{Environment.NewLine} Read database resource: {DatabaseName}");
database = client.GetDatabase(DatabaseName);
Console.WriteLine($"{Environment.NewLine} database { database.Id.ToString()}");

// Read all databases
string findQueryText = "SELECT * FROM c";
using (FeedIterator<DatabaseProperties> feedIterator = client.GetDatabaseQueryIterator<DatabaseProperties>
(findQueryText))
{
    while (feedIterator.HasMoreResults)
    {
        FeedResponse<DatabaseProperties> databaseResponses = await feedIterator.ReadNextAsync();
        foreach (DatabaseProperties _database in databaseResponses)
        {
            Console.WriteLine($"{ Environment.NewLine} database {_database.Id.ToString()}");
        }
    }
}
```

Delete a database

- .NET SDK v3
- .NET SDK v2

```
// Delete a database
await client.GetDatabase(DatabaseName).DeleteAsync();
Console.WriteLine($"{ Environment.NewLine} database {DatabaseName} deleted.");

// Delete all databases in an account
string deleteQueryText = "SELECT * FROM c";
using (FeedIterator<DatabaseProperties> feedIterator = client.GetDatabaseQueryIterator<DatabaseProperties>
(deleteQueryText))
{
    while (feedIterator.HasMoreResults)
    {
        FeedResponse<DatabaseProperties> databaseResponses = await feedIterator.ReadNextAsync();
        foreach (DatabaseProperties _database in databaseResponses)
        {
            await client.GetDatabase(_database.Id).DeleteAsync();
            Console.WriteLine($"{ Environment.NewLine} database {_database.Id} deleted");
        }
    }
}
```

Container operations

Create a container (Autoscale + Time to live with expiration)

- .NET SDK v3
- .NET SDK v2

```
private static async Task CreateManualThroughputContainer(Database database)
{
    // Set throughput to the minimum value of 400 RU/s manually configured throughput
    string containerIdManual = ContainerName + "_Manual";
    ContainerResponse container = await database.CreateContainerIfNotExistsAsync(
        id: containerIdManual,
        partitionKeyPath: partitionKeyPath,
        throughput: 400);
}

// Create container with autoscale
private static async Task CreateAutoscaleThroughputContainer(Database database)
{
    string autoscaleContainerId = ContainerName + "_Autoscale";
    ContainerProperties containerProperties = new ContainerProperties(autoscaleContainerId, partitionKeyPath);

    Container container = await database.CreateContainerIfNotExistsAsync(
        containerProperties: containerProperties,
        throughputProperties: ThroughputProperties.CreateAutoscaleThroughput(autoscaleMaxThroughput: 4000);
}

// Create a container with TTL Expiration
private static async Task CreateContainerWithTtlExpiration(Database database)
{
    string containerIdManualwithTTL = ContainerName + "_ManualTTL";

    ContainerProperties properties = new ContainerProperties
        (id: containerIdManualwithTTL,
        partitionKeyPath: partitionKeyPath);

    properties.DefaultTimeToLive = (int)TimeSpan.FromDays(1).TotalSeconds; //expire in 1 day

    ContainerResponse containerResponse = await database.CreateContainerIfNotExistsAsync(containerProperties:
properties);
    ContainerProperties returnedProperties = containerResponse;
}
```

Read container properties

- .NET SDK v3
- .NET SDK v2

```
private static async Task ReadContainerProperties(Database database)
{
    string containerIdManual = ContainerName + "_Manual";
    Container container = database.GetContainer(containerIdManual);
    ContainerProperties containerProperties = await container.ReadContainerAsync();
}
```

Delete a container

- .NET SDK v3
- .NET SDK v2

```
private static async Task DeleteContainers(Database database)
{
    string containerIdManual = ContainerName + "_Manual";

    // Delete a container
    await database.GetContainer(containerIdManual).DeleteContainerAsync();

    // Delete all CosmosContainer resources for a database
    using (FeedIterator<ContainerProperties> feedIterator =
database.GetContainerQueryIterator<ContainerProperties>())
    {
        while (feedIterator.HasMoreResults)
        {
            foreach (ContainerProperties _container in await feedIterator.ReadNextAsync())
            {
                await database.GetContainer(_container.Id).DeleteContainerAsync();
                Console.WriteLine($"{Environment.NewLine}  deleted container {_container.Id}");
            }
        }
    }
}
```

Item and query operations

Create an item

- .NET SDK v3
- .NET SDK v2

```
private static async Task CreateItemAsync(Container container)
{
    // Create a SalesOrder POCO object
    SalesOrder salesOrder1 = GetSalesOrderSample("Account1", "SalesOrder1");
    ItemResponse<SalesOrder> response = await container.CreateItemAsync(salesOrder1,
        new PartitionKey(salesOrder1.AccountNumber));
}

private static async Task RunBasicOperationsOnDynamicObjects(Container container)
{
    // Dynamic Object
    dynamic salesOrder = new
    {
        id = "SalesOrder5",
        AccountNumber = "Account1",
        PurchaseOrderNumber = "PO18009186470",
        OrderDate = DateTime.UtcNow,
        Total = 5.95,
    };
    Console.WriteLine("\nCreating item");
    ItemResponse<dynamic> response = await container.CreateItemAsync<dynamic>(
        salesOrder, new PartitionKey(salesOrder.AccountNumber));
    dynamic createdSalesOrder = response.Resource;
}
```

Read all the items in a container

- .NET SDK v3
- .NET SDK v2

```
private static async Task ReadAllItems(Container container)
{
    // Read all items in a container
    List<SalesOrder> allSalesForAccount1 = new List<SalesOrder>();

    using (FeedIterator<SalesOrder> resultSet = container.GetItemQueryIterator<SalesOrder>(
        queryDefinition: null,
        requestOptions: new QueryRequestOptions()
        {
            PartitionKey = new PartitionKey("Account1"),
            MaxItemCount = 5
        }))
    {
        while (resultSet.HasMoreResults)
        {
            FeedResponse<SalesOrder> response = await resultSet.ReadNextAsync();
            SalesOrder salesOrder = response.First();
            Console.WriteLine($"\n1.3.1 Account Number: {salesOrder.AccountNumber}; Id: {salesOrder.Id}");
            allSalesForAccount1.AddRange(response);
        }
    }
}
```

Query items

- .NET SDK v3
- .NET SDK v2

```
private static async Task QueryItems(Container container)
{
    // Query for items by a property other than Id
    QueryDefinition queryDefinition = new QueryDefinition(
        "select * from sales s where s.AccountNumber = @AccountInput")
        .WithParameter("@AccountInput", "Account1");

    List<SalesOrder> allSalesForAccount1 = new List<SalesOrder>();
    using (FeedIterator<SalesOrder> resultSet = container.GetItemQueryIterator<SalesOrder>(
        queryDefinition,
        requestOptions: new QueryRequestOptions()
        {
            PartitionKey = new PartitionKey("Account1"),
            MaxItemCount = 1
        }))
    {
        while (resultSet.HasMoreResults)
        {
            FeedResponse<SalesOrder> response = await resultSet.ReadNextAsync();
            SalesOrder sale = response.First();
            Console.WriteLine($"\n Account Number: {sale.AccountNumber}; Id: {sale.Id};");
            allSalesForAccount1.AddRange(response);
        }
    }
}
```

Delete an item

- .NET SDK v3
- .NET SDK v2

```
private static async Task DeleteItemAsync(Container container)
{
    ItemResponse<SalesOrder> response = await container.DeleteItemAsync<SalesOrder>(
        partitionKey: new PartitionKey("Account1"), id: "SalesOrder3");
}
```

Migrate your application to use the Azure Cosmos DB .NET SDK v2

12/4/2020 • 2 minutes to read • Edit Online

> **IMPORTANT**
>
> It is important to note that the v3 of the .NET SDK is currently available and a migration plan from v2 to v3 is available here. To learn about the Azure Cosmos DB .NET SDK v2, see the Release notes, the .NET GitHub repository, .NET SDK v2 Performance Tips, and the Troubleshooting guide.

This article highlights some of the considerations to upgrade your existing v1 .NET application to Azure Cosmos DB .NET SDK v2 for Core (SQL) API. Azure Cosmos DB .NET SDK v2 corresponds to the `Microsoft.Azure.DocumentDB` namespace. You can use the information provided in this document if you are migrating your application from any of the following Azure Cosmos DB .NET Platforms to use the v2 SDK `Microsoft.Azure.Cosmos`:

- Azure Cosmos DB .NET Framework v1 SDK for SQL API
- Azure Cosmos DB .NET Core SDK v1 for SQL API

What's available in the .NET v2 SDK

The v2 SDK contains many usability and performance improvements, including:

- Support for TCP direct mode for non-Windows clients
- Multi-region write support
- Improvements on query performance
- Support for geospatial/geometry collections and indexing
- Increased improvements for direct/TCP transport diagnostics
- Updates on direct TCP transport stack to reduce the number of connections established
- Improvements in latency reduction in the RequestTimeout

Most of the retry logic and lower levels of the SDK remains largely unchanged.

Why migrate to the .NET v2 SDK

In addition to the numerous performance improvements, new feature investments made in the latest SDK will not be back ported to older versions.

Additionally, the older SDKs will be replaced by newer versions and the v1 SDK will go into maintenance mode. For the best development experience, we recommend migrating your application to a later version of the SDK.

Major changes from v1 SDK to v2 SDK

Direct mode + TCP

The .NET v2 SDK now supports both direct and gateway mode. Direct mode supports connectivity through TCP protocol and offers better performance as it connects directly to the backend replicas with fewer network hops.

For more details, read through the Azure Cosmos DB SQL SDK connectivity modes guide.

Session token formatting

The v2 SDK no longer uses the *simple* session token format as used in v1, instead the SDK uses *vector* formatting. The format should be converted when passing to the client application with different versions, since the formats are not interchangeable.

For more information, see converting session token formats in the .NET SDK.

Using the .NET change feed processor SDK

The .NET change feed processor library 2.1.x requires `Microsoft.Azure.DocumentDB` 2.0 or later.

The 2.1.x library has the following key changes:

- Stability and diagnosability improvements
- Improved handling of errors and exceptions
- Additional support for partitioned lease collections
- Advanced extensions to implement the `ChangeFeedDocument` interface and class for additional error handling and tracing
- Added support for using a custom store to persist continuation tokens per partition

For more information, see the change feed processor library release notes.

Using the bulk executor library

The v2 bulk executor library currently has a dependency on the Azure Cosmos DB .NET SDK 2.5.1 or later.

For more information, see the Azure Cosmos DB bulk executor library overview and the .NET bulk executor library release notes.

Troubleshoot query issues when using Azure Cosmos DB

12/4/2020 • 14 minutes to read • Edit Online

APPLIES TO: SQL API

This article walks through a general recommended approach for troubleshooting queries in Azure Cosmos DB. Although you shouldn't consider the steps outlined in this article a complete defense against potential query issues, we've included the most common performance tips here. You should use this article as a starting place for troubleshooting slow or expensive queries in the Azure Cosmos DB core (SQL) API. You can also use diagnostics logs to identify queries that are slow or that consume significant amounts of throughput. If you are using Azure Cosmos DB's API for MongoDB, you should use Azure Cosmos DB's API for MongoDB query troubleshooting guide

Query optimizations in Azure Cosmos DB are broadly categorized as follows:

- Optimizations that reduce the Request Unit (RU) charge of the query
- Optimizations that just reduce latency

If you reduce the RU charge of a query, you'll typically decrease latency as well.

This article provides examples that you can re-create by using the nutrition dataset.

Common SDK issues

Before reading this guide, it is helpful to consider common SDK issues that aren't related to the query engine.

- Follow these SDK Performance tips.
  - .NET SDK troubleshooting guide
  - Java SDK troubleshooting guide
- The SDK allows setting a `MaxItemCount` for your queries but you can't specify a minimum item count.
  - Code should handle any page size, from zero to the `MaxItemCount`.
- Sometimes queries may have empty pages even when there are results on a future page. Reasons for this could be:
  - The SDK could be doing multiple network calls.
  - The query might be taking a long time to retrieve the documents.
- All queries have a continuation token that will allow the query to continue. Be sure to drain the query completely. Learn more about handling multiple pages of results

Get query metrics

When you optimize a query in Azure Cosmos DB, the first step is always to get the query metrics for your query. These metrics are also available through the Azure portal. Once you run your query in the Data Explorer, the query metrics are visible next to the **Results** tab:

After you get the query metrics, compare the **Retrieved Document Count** with the **Output Document Count** for your query. Use this comparison to identify the relevant sections to review in this article.

The **Retrieved Document Count** is the number of documents that the query engine needed to load. The **Output Document Count** is the number of documents that were needed for the results of the query. If the **Retrieved Document Count** is significantly higher than the **Output Document Count**, there was at least one part of your query that was unable to use an index and needed to do a scan.

Refer to the following sections to understand the relevant query optimizations for your scenario.

Query's RU charge is too high

Retrieved Document Count is significantly higher than Output Document Count

- Include necessary paths in the indexing policy.
- Understand which system functions use the index.
- Understand which aggregate queries use the index.
- Optimize queries that have both a filter and an ORDER BY clause.
- Optimize JOIN expressions by using a subquery.

Retrieved Document Count is approximately equal to Output Document Count

- Minimize cross partition queries.
- Optimize queries that have filters on multiple properties.
- Optimize queries that have both a filter and an ORDER BY clause.

Query's RU charge is acceptable but latency is still too high

- Improve proximity.
- Increase provisioned throughput.
- Increase MaxConcurrency.
- Increase MaxBufferedItemCount.

Queries where Retrieved Document Count exceeds Output Document

Count

The **Retrieved Document Count** is the number of documents that the query engine needed to load. The **Output Document Count** is the number of documents returned by the query. If the **Retrieved Document Count** is significantly higher than the **Output Document Count**, there was at least one part of your query that was unable to use an index and needed to do a scan.

Here's an example of scan query that wasn't entirely served by the index:

Query:

```
SELECT VALUE c.description
FROM c
WHERE UPPER(c.description) = "BABYFOOD, DESSERT, FRUIT DESSERT, WITHOUT ASCORBIC ACID, JUNIOR"
```

Query metrics:

```
Retrieved Document Count                  :          60,951
Retrieved Document Size                   :     399,998,938 bytes
Output Document Count                     :               7
Output Document Size                      :             510 bytes
Index Utilization                         :            0.00 %
Total Query Execution Time                :        4,500.34 milliseconds
  Query Preparation Times
    Query Compilation Time                :            0.09 milliseconds
    Logical Plan Build Time               :            0.05 milliseconds
    Physical Plan Build Time              :            0.04 milliseconds
    Query Optimization Time               :            0.01 milliseconds
  Index Lookup Time                       :            0.01 milliseconds
  Document Load Time                      :        4,177.66 milliseconds
  Runtime Execution Times
    Query Engine Times                    :          322.16 milliseconds
    System Function Execution Time        :           85.74 milliseconds
    User-defined Function Execution Time  :            0.00 milliseconds
  Document Write Time                     :            0.01 milliseconds
Client Side Metrics
  Retry Count                             :               0
  Request Charge                          :        4,059.95 RUs
```

The **Retrieved Document Count** (60,951) is significantly higher than the **Output Document Count** (7), implying that this query resulted in a document scan. In this case, the system function UPPER() doesn't use an index.

Include necessary paths in the indexing policy

Your indexing policy should cover any properties included in `WHERE` clauses, `ORDER BY` clauses, `JOIN`, and most system functions. The desired paths specified in the index policy should match the properties in the JSON documents.

> **NOTE**
>
> Properties in Azure Cosmos DB indexing policy are case-sensitive

If you run the following simple query on the nutrition dataset, you will observe a much lower RU charge when the property in the `WHERE` clause is indexed:

Original

Query:

```
SELECT *
FROM c
WHERE c.description = "Malabar spinach, cooked"
```

Indexing policy:

```
{
    "indexingMode": "consistent",
    "automatic": true,
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "excludedPaths": [
        {
            "path": "/description/*"
        }
    ]
}
```

RU charge: 409.51 RUs

Optimized

Updated indexing policy:

```
{
    "indexingMode": "consistent",
    "automatic": true,
    "includedPaths": [
        {
            "path": "/*"
        }
    ],
    "excludedPaths": []
}
```

RU charge: 2.98 RUs

You can add properties to the indexing policy at any time, with no effect on write or read availability. You can track index transformation progress.

Understand which system functions use the index

If an expression can be translated into a range of string values, it can use the index. Otherwise, it can't.

Here's the list of some common string functions that can use the index:

- STARTSWITH(str_expr1, str_expr2, bool_expr)
- CONTAINS(str_expr, str_expr, bool_expr)
- LEFT(str_expr, num_expr) = str_expr
- SUBSTRING(str_expr, num_expr, num_expr) = str_expr, but only if the first num_expr is 0

Following are some common system functions that don't use the index and must load each document:

SYSTEM FUNCTION	IDEAS FOR OPTIMIZATION

SYSTEM FUNCTION	IDEAS FOR OPTIMIZATION
UPPER/LOWER	Instead of using the system function to normalize data for comparisons, normalize the casing upon insertion. A query like `SELECT * FROM c WHERE UPPER(c.name) = 'BOB'` becomes `SELECT * FROM c WHERE c.name = 'BOB'`.
Mathematical functions (non-aggregates)	If you need to compute a value frequently in your query, consider storing the value as a property in your JSON document.

Other parts of the query might still use the index even though the system functions don't.

Understand which aggregate queries use the index

In most cases, aggregate system functions in Azure Cosmos DB will use the index. However, depending on the filters or additional clauses in an aggregate query, the query engine may be required to load a high number of documents. Typically, the query engine will apply equality and range filters first. After applying these filters, the query engine can evaluate additional filters and resort to loading remaining documents to compute the aggregate, if needed.

For example, given these two sample queries, the query with both an equality and `CONTAINS` system function filter will generally be more efficient than a query with just a `CONTAINS` system function filter. This is because the equality filter is applied first and uses the index before documents need to be loaded for the more expensive `CONTAINS` filter.

Query with only `CONTAINS` filter - higher RU charge:

```
SELECT COUNT(1)
FROM c
WHERE CONTAINS(c.description, "spinach")
```

Query with both equality filter and `CONTAINS` filter - lower RU charge:

```
SELECT AVG(c._ts)
FROM c
WHERE c.foodGroup = "Sausages and Luncheon Meats" AND CONTAINS(c.description, "spinach")
```

Here are additional examples of aggregate queries that will not fully use the index:

Queries with system functions that don't use the index

You should refer to the relevant system function's page to see if it uses the index.

```
SELECT MAX(c._ts)
FROM c
WHERE CONTAINS(c.description, "spinach")
```

Aggregate queries with user-defined functions(UDF's)

```
SELECT AVG(c._ts)
FROM c
WHERE udf.MyUDF("Sausages and Luncheon Meats")
```

Queries with GROUP BY

The RU charge of queries with `GROUP BY` will increase as the cardinality of the properties in the `GROUP BY` clause increases. In the below query, for example, the RU charge of the query will increase as the number unique

descriptions increases.

The RU charge of an aggregate function with a `GROUP BY` clause will be higher than the RU charge of an aggregate function alone. In this example, the query engine must load every document that matches the `c.foodGroup = "Sausages and Luncheon Meats"` filter so the RU charge is expected to be high.

```
SELECT COUNT(1)
FROM c
WHERE c.foodGroup = "Sausages and Luncheon Meats"
GROUP BY c.description
```

If you plan to frequently run the same aggregate queries, it may be more efficient to build a real-time materialized view with the Azure Cosmos DB change feed than running individual queries.

Optimize queries that have both a filter and an ORDER BY clause

Although queries that have a filter and an `ORDER BY` clause will normally use a range index, they'll be more efficient if they can be served from a composite index. In addition to modifying the indexing policy, you should add all properties in the composite index to the `ORDER BY` clause. This change to the query will ensure that it uses the composite index. You can observe the impact by running a query on the nutrition dataset:

Original

Query:

```
SELECT *
FROM c
WHERE c.foodGroup = "Soups, Sauces, and Gravies"
ORDER BY c._ts ASC
```

Indexing policy:

```
{

        "automatic":true,
        "indexingMode":"Consistent",
        "includedPaths":[
            {
                "path":"/*"
            }
        ],
        "excludedPaths":[]
}
```

RU charge: 44.28 RUs

Optimized

Updated query (includes both properties in the `ORDER BY` clause):

```
SELECT *
FROM c
WHERE c.foodGroup = "Soups, Sauces, and Gravies"
ORDER BY c.foodGroup, c._ts ASC
```

Updated indexing policy:

```
{
        "automatic":true,
        "indexingMode":"Consistent",
        "includedPaths":[
            {
                "path":"/*"
            }
        ],
        "excludedPaths":[],
        "compositeIndexes":[
            [
                {
                    "path":"/foodGroup",
                    "order":"ascending"
        },
                {
                    "path":"/_ts",
                    "order":"ascending"
                }
            ]
        ]
    }
```

RU charge: 8.86 RUs

Optimize JOIN expressions by using a subquery

Multi-value subqueries can optimize `JOIN` expressions by pushing predicates after each select-many expression rather than after all cross joins in the `WHERE` clause.

Consider this query:

```
SELECT Count(1) AS Count
FROM c
JOIN t IN c.tags
JOIN n IN c.nutrients
JOIN s IN c.servings
WHERE t.name = 'infant formula' AND (n.nutritionValue > 0
AND n.nutritionValue < 10) AND s.amount > 1
```

RU charge: 167.62 RUs

For this query, the index will match any document that has a tag with the name `infant formula`, `nutritionValue` greater than 0, and `amount` greater than 1. The `JOIN` expression here will perform the cross-product of all items of tags, nutrients, and servings arrays for each matching document before any filter is applied. The `WHERE` clause will then apply the filter predicate on each `<c, t, n, s>` tuple.

For example, if a matching document has 10 items in each of the three arrays, it will expand to 1 x 10 x 10 x 10 (that is, 1,000) tuples. The use of subqueries here can help to filter out joined array items before joining with the next expression.

This query is equivalent to the preceding one but uses subqueries:

```
SELECT Count(1) AS Count
FROM c
JOIN (SELECT VALUE t FROM t IN c.tags WHERE t.name = 'infant formula')
JOIN (SELECT VALUE n FROM n IN c.nutrients WHERE n.nutritionValue > 0 AND n.nutritionValue < 10)
JOIN (SELECT VALUE s FROM s IN c.servings WHERE s.amount > 1)
```

RU charge: 22.17 RUs

Assume that only one item in the tags array matches the filter and that there are five items for both the nutrients and servings arrays. The `JOIN` expressions will expand to 1 x 1 x 5 x 5 = 25 items, as opposed to 1,000 items in the first query.

Queries where Retrieved Document Count is equal to Output Document Count

If the **Retrieved Document Count** is approximately equal to the **Output Document Count**, the query engine didn't have to scan many unnecessary documents. For many queries, like those that use the `TOP` keyword, **Retrieved Document Count** might exceed **Output Document Count** by 1. You don't need to be concerned about this.

Minimize cross partition queries

Azure Cosmos DB uses partitioning to scale individual containers as Request Unit and data storage needs increase. Each physical partition has a separate and independent index. If your query has an equality filter that matches your container's partition key, you'll need to check only the relevant partition's index. This optimization reduces the total number of RUs that the query requires.

If you have a large number of provisioned RUs (more than 30,000) or a large amount of data stored (more than approximately 100 GB), you probably have a large enough container to see a significant reduction in query RU charges.

For example, if you create a container with the partition key foodGroup, the following queries will need to check only a single physical partition:

```
SELECT *
FROM c
WHERE c.foodGroup = "Soups, Sauces, and Gravies" and c.description = "Mushroom, oyster, raw"
```

Queries that have an `IN` filter with the partition key will only check the relevant physical partition(s) and will not "fan-out":

```
SELECT *
FROM c
WHERE c.foodGroup IN("Soups, Sauces, and Gravies", "Vegetables and Vegetable Products") and c.description =
"Mushroom, oyster, raw"
```

Queries that have range filters on the partition key, or that don't have any filters on the partition key, will need to "fan-out" and check every physical partition's index for results:

```
SELECT *
FROM c
WHERE c.description = "Mushroom, oyster, raw"
```

```
SELECT *
FROM c
WHERE c.foodGroup > "Soups, Sauces, and Gravies" and c.description = "Mushroom, oyster, raw"
```

Optimize queries that have filters on multiple properties

Although queries that have filters on multiple properties will normally use a range index, they'll be more efficient if they can be served from a composite index. For small amounts of data, this optimization won't have a significant impact. It could be useful, however, for large amounts of data. You can only optimize, at most, one non-equality filter per composite index. If your query has multiple non-equality filters, pick one of them that will use the

composite index. The rest will continue to use range indexes. The non-equality filter must be defined last in the composite index. Learn more about composite indexes.

Here are some examples of queries that could be optimized with a composite index:

```
SELECT *
FROM c
WHERE c.foodGroup = "Vegetables and Vegetable Products" AND c._ts = 1575503264
```

```
SELECT *
FROM c
WHERE c.foodGroup = "Vegetables and Vegetable Products" AND c._ts > 1575503264
```

Here's the relevant composite index:

```
{
        "automatic":true,
        "indexingMode":"Consistent",
        "includedPaths":[
            {
                "path":"/*"
            }
        ],
        "excludedPaths":[],
        "compositeIndexes":[
            [
                {
                    "path":"/foodGroup",
                    "order":"ascending"
                },
                {
                    "path":"/_ts",
                    "order":"ascending"
                }
            ]
        ]
}
```

Optimizations that reduce query latency

In many cases, the RU charge might be acceptable when query latency is still too high. The following sections give an overview of tips for reducing query latency. If you run the same query multiple times on the same dataset, it will typically have the same RU charge each time. But query latency might vary between query executions.

Improve proximity

Queries that are run from a different region than the Azure Cosmos DB account will have higher latency than if they were run inside the same region. For example, if you're running code on your desktop computer, you should expect latency to be tens or hundreds of milliseconds higher (or more) than if the query came from a virtual machine within the same Azure region as Azure Cosmos DB. It's simple to globally distribute data in Azure Cosmos DB to ensure you can bring your data closer to your app.

Increase provisioned throughput

In Azure Cosmos DB, your provisioned throughput is measured in Request Units (RUs). Imagine you have a query that consumes 5 RUs of throughput. For example, if you provision 1,000 RUs, you would be able to run that query 200 times per second. If you tried to run the query when there wasn't enough throughput available, Azure Cosmos DB would return an HTTP 429 error. Any of the current Core (SQL) API SDKs will automatically retry this query after waiting for a short time. Throttled requests take longer, so increasing provisioned throughput can improve

query latency. You can observe the total number of throttled requests on the **Metrics** blade of the Azure portal.

Increase MaxConcurrency

Parallel queries work by querying multiple partitions in parallel. But data from an individual partitioned collection is fetched serially with respect to the query. So, if you set MaxConcurrency to the number of partitions, you have the best chance of achieving the most performant query, provided all other system conditions remain the same. If you don't know the number of partitions, you can set MaxConcurrency (or MaxDegreesOfParallelism in older SDK versions) to a high number. The system will choose the minimum (number of partitions, user provided input) as the maximum degree of parallelism.

Increase MaxBufferedItemCount

Queries are designed to pre-fetch results while the current batch of results is being processed by the client. Pre-fetching helps to improve the overall latency of a query. Setting MaxBufferedItemCount limits the number of pre-fetched results. If you set this value to the expected number of results returned (or a higher number), the query can get the most benefit from pre-fetching. If you set this value to -1, the system will automatically determine the number of items to buffer.

Diagnose and troubleshoot Azure Cosmos DB request timeout exceptions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB returned an HTTP 408 request timeout.

Troubleshooting steps

The following list contains known causes and solutions for request timeout exceptions.

Check the SLA

Check Azure Cosmos DB monitoring to see if the number of 408 exceptions violates the Azure Cosmos DB SLA.

Solution 1: It didn't violate the Azure Cosmos DB SLA

The application should handle this scenario and retry on these transient failures.

Solution 2: It did violate the Azure Cosmos DB SLA

Contact Azure Support.

Hot partition key

Azure Cosmos DB distributes the overall provisioned throughput evenly across physical partitions. When there's a hot partition, one or more logical partition keys on a physical partition are consuming all the physical partition's Request Units per second (RU/s). At the same time, the RU/s on other physical partitions are going unused. As a symptom, the total RU/s consumed will be less than the overall provisioned RU/s at the database or container. You'll still see throttling (429s) on the requests against the hot logical partition key. Use the Normalized RU Consumption metric to see if the workload is encountering a hot partition.

Solution:

Choose a good partition key that evenly distributes request volume and storage. Learn how to change your partition key.

Diagnose and troubleshoot Azure Cosmos DB request rate too large exceptions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

A "Request rate too large" message or error code 429 indicates that your requests are being throttled.

Troubleshooting steps

The following section contains known causes and solutions for too many requests.

Check the metrics

Check Azure Cosmos DB monitoring to see the number of 429 exceptions.

Cause:

The consumed throughput (Request Units per second) has exceeded the provisioned throughput. The SDK automatically retries requests based on the specified retry policy. If you get this failure often, consider increasing the throughput on the collection. Check the portal's metrics to see if you're getting 429 errors. Review your partition key to ensure it results in an even distribution of storage and request volume.

Solution:

1. Use the portal or the SDK to increase the provisioned throughput.
2. Switch the database or container to Autoscale.

Next steps

Diagnose and troubleshoot Azure Cosmos DB not found exceptions

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

The HTTP status code 404 represents that the resource no longer exists.

Expected behavior

There are many valid scenarios where an application expects a code 404 and correctly handles the scenario.

A not found exception was returned for an item that should exist or does exist

Here are the possible reasons for a status code 404 to be returned if the item should exist or does exist.

The read session is not available for the input session token

Solution:

1. Update your current SDK to the latest version available. The most common causes for this particular error have been fixed in the newest SDK versions.

Race condition

There are multiple SDK client instances and the read happened before the write.

Solution:

1. The default account consistency for Azure Cosmos DB is session consistency. When an item is created or updated, the response returns a session token that can be passed between SDK instances to guarantee that the read request is reading from a replica with that change.
2. Change the consistency level to a stronger level.

Invalid partition key and ID combination

The partition key and ID combination aren't valid.

Solution:

Fix the application logic that's causing the incorrect combination.

Invalid character in an item ID

An item is inserted into Azure Cosmos DB with an invalid character in the item ID.

Solution:

Change the ID to a different value that doesn't contain the special characters. If changing the ID isn't an option, you can Base64 encode the ID to escape the special characters. Base64 can still produce a name with a invalid character '/' which needs to be replaced.

Items already inserted in the container for the ID can be replaced by using RID values instead of name-based references.

```
// Get a container reference that uses RID values.
ContainerProperties containerProperties = await this.Container.ReadContainerAsync();
string[] selfLinkSegments = containerProperties.SelfLink.Split('/');
string databaseRid = selfLinkSegments[1];
string containerRid = selfLinkSegments[3];
Container containerByRid = this.cosmosClient.GetContainer(databaseRid, containerRid);

// Invalid characters are listed here.
//https://docs.microsoft.com/dotnet/api/microsoft.azure.documents.resource.id?view=azure-dotnet&preserve-
view=true#remarks
FeedIterator<JObject> invalidItemsIterator = this.Container.GetItemQueryIterator<JObject>(
    @"select * from t where CONTAINS(t.id, ""/"") or CONTAINS(t.id, ""#"") or CONTAINS(t.id, ""?"") or
CONTAINS(t.id, ""\\"") ");
while (invalidItemsIterator.HasMoreResults)
{
    foreach (JObject itemWithInvalidId in await invalidItemsIterator.ReadNextAsync())
    {
        // Choose a new ID that doesn't contain special characters.
        // If that isn't possible, then Base64 encode the ID to escape the special characters.
        byte[] plainTextBytes = Encoding.UTF8.GetBytes(itemWithInvalidId["id"].ToString());
        itemWithInvalidId["id"] = Convert.ToBase64String(plainTextBytes).Replace('/', '!');

        // Update the item with the new ID value by using the RID-based container reference.
        JObject item = await containerByRid.ReplaceItemAsync<JObject>(
            item: itemWithInvalidId,
            ID: itemWithInvalidId["_rid"].ToString(),
            partitionKey: new Cosmos.PartitionKey(itemWithInvalidId["status"].ToString()));

        // Validating the new ID can be read by using the original name-based container reference.
        await this.Container.ReadItemAsync<ToDoActivity>(
            item["id"].ToString(),
            new Cosmos.PartitionKey(item["status"].ToString())); ;
    }
}
```

Time to Live purge

The item had the Time to Live (TTL) property set. The item was purged because the TTL property expired.

Solution:

Change the TTL property to prevent the item from being purged.

Lazy indexing

The lazy indexing hasn't caught up.

Solution:

Wait for the indexing to catch up or change the indexing policy.

Parent resource deleted

The database or container that the item exists in was deleted.

Solution:

1. Restore the parent resource, or re-create the resources.
2. Create a new resource to replace the deleted resource.

7. Container/Collection names are case-sensitive

Container/Collection names are case-sensitive in Cosmos DB.

Solution:

Make sure to use the exact name while connecting to Cosmos DB.

Diagnose and troubleshoot Azure Cosmos DB unauthorized exceptions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

HTTP 401: The MAC signature found in the HTTP request isn't the same as the computed signature. If you received the 401 error message "The MAC signature found in the HTTP request is not the same as the computed signature," it can be caused by the following scenarios.

For older SDKs, the exception can appear as an invalid JSON exception instead of the correct 401 unauthorized exception. Newer SDKs properly handle this scenario and give a valid error message.

Troubleshooting steps

The following list contains known causes and solutions for unauthorized exceptions.

The key wasn't properly rotated is the most common scenario

The 401 MAC signature is seen shortly after a key rotation and eventually stops without any changes.

Solution:

The key was rotated and didn't follow the best practices. The Azure Cosmos DB account key rotation can take anywhere from a few seconds to possibly days depending on the Azure Cosmos DB account size.

The key is misconfigured

The 401 MAC signature issue will be consistent and happens for all calls using that key.

Solution:

The key is misconfigured on the application and is using the wrong key for the account, or the entire key wasn't copied.

The application is using the read-only keys for write operations

The 401 MAC signature issue only occurs for write operations like create or replace, but read requests succeed.

Solution:

Switch the application to use a read/write key to allow the operations to complete successfully.

Race condition with create container

The 401 MAC signature issue is seen shortly after a container creation. This issue occurs only until the container creation is completed.

Solution:

There's a race condition with container creation. An application instance is trying to access the container before the container creation is complete. The most common scenario for this race condition is if the application is running and the container is deleted and re-created with the same name. The SDK attempts to use the new container, but the container creation is still in progress so it doesn't have the keys.

Diagnose and troubleshoot the availability of Azure Cosmos SDKs in multiregional environments

11/2/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes the behavior of the latest version of Azure Cosmos SDKs when you see a connectivity issue to a particular region or when a region failover occurs.

All the Azure Cosmos SDKs give you an option to customize the regional preference. The following properties are used in different SDKs:

- The ConnectionPolicy.PreferredLocations property in .NET V2 SDK.
- The CosmosClientOptions.ApplicationRegion or CosmosClientOptions.ApplicationPreferredRegions properties in .NET V3 SDK.
- The CosmosClientBuilder.preferredRegions method in Java V4 SDK.
- The CosmosClient.preferred_locations parameter in Python SDK.
- The CosmosClientOptions.ConnectionPolicy.preferredLocations parameter in JS SDK.

When you set the regional preference, the client will connect to a region as mentioned in the following table:

ACCOUNT TYPE	READS	WRITES
Single write region	Preferred region	Primary region
Multiple write regions	Preferred region	Preferred region

If you **don't set a preferred region**, the SDK client defaults to the primary region:

ACCOUNT TYPE	READS	WRITES
Single write region	Primary region	Primary region
Multiple write regions	Primary region	Primary region

> **NOTE**
> Primary region refers to the first region in the Azure Cosmos account region list

Under normal circumstances, the SDK client will connect to the preferred region (if a regional preference is set) or to the primary region (if no preference is set), and the operations will be limited to that region, unless any of the below scenarios occur.

In these cases, the client using the Azure Cosmos SDK exposes logs and includes the retry information as part of the **operation diagnostic information**:

- The *RequestDiagnosticsString* property on responses in .NET V2 SDK.
- The *Diagnostics* property on responses and exceptions in .NET V3 SDK.
- The *getDiagnostics()* method on responses and exceptions in Java V4 SDK.

When determining the next region in order of preference, the SDK client will use the account region list, prioritizing the preferred regions (if any).

For a comprehensive detail on SLA guarantees during these events, see the SLAs for availability.

Removing a region from the account

When you remove a region from an Azure Cosmos account, any SDK client that actively uses the account will detect the region removal through a backend response code. The client then marks the regional endpoint as unavailable. The client retries the current operation and all the future operations are permanently routed to the next region in order of preference.

Adding a region to an account

Every 5 minutes, the Azure Cosmos SDK client reads the account configuration and refreshes the regions that it's aware of.

If you remove a region and later add it back to the account, if the added region has a higher regional preference order in the SDK configuration than the current connected region, the SDK will switch back to use this region permanently. After the added region is detected, all the future requests are directed to it.

If you configure the client to preferably connect to a region that the Azure Cosmos account does not have, the preferred region is ignored. If you add that region later, the client detects it and will switch permanently to that region.

Fail over the write region in a single write region account

If you initiate a failover of the current write region, the next write request will fail with a known backend response. When this response is detected, the client will query the account to learn the new write region and proceeds to retry the current operation and permanently route all future write operations to the new region.

Regional outage

If the account is single write region and the regional outage occurs during a write operation, the behavior is similar to a manual failover. For read requests or multiple write regions accounts, the behavior is similar to removing a region.

Session consistency guarantees

When using session consistency, the client needs to guarantee that it can read its own writes. In single write region accounts where the read region preference is different from the write region, there could be cases where the user issues a write and when doing a read from a local region, the local region has not yet received the data replication (speed of light constraint). In such cases, the SDK detects the specific failure on the read operation and retries the read on the primary region to ensure session consistency.

Transient connectivity issues on TCP protocol

In scenarios where the Azure Cosmos SDK client is configured to use the TCP protocol, for a given request, there might be situations where the network conditions are temporarily affecting the communication with a particular endpoint. These temporary network conditions can surface as TCP timeouts. The client will retry the request locally on the same endpoint for some seconds.

If the user has configured a preferred region list with more than one region and the Azure Cosmos account is multiple write regions or single write region and the operation is a read request, the client will retry that single operation in the next region from the preference list.

Next steps

- Review the Availability SLAs.
- Use the latest .NET SDK

Diagnose and troubleshoot issues when using Azure Cosmos DB .NET SDK

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This article covers common issues, workarounds, diagnostic steps, and tools when you use the .NET SDK with Azure Cosmos DB SQL API accounts. The .NET SDK provides client-side logical representation to access the Azure Cosmos DB SQL API. This article describes tools and approaches to help you if you run into any issues.

Checklist for troubleshooting issues

Consider the following checklist before you move your application to production. Using the checklist will prevent several common issues you might see. You can also quickly diagnose when an issue occurs:

- Use the latest SDK. Preview SDKs should not be used for production. This will prevent hitting known issues that are already fixed.
- Review the performance tips, and follow the suggested practices. This will help prevent scaling, latency, and other performance issues.
- Enable the SDK logging to help you troubleshoot an issue. Enabling the logging may affect performance so it's best to enable it only when troubleshooting issues. You can enable the following logs:
- Log metrics by using the Azure portal. Portal metrics show the Azure Cosmos DB telemetry, which is helpful to determine if the issue corresponds to Azure Cosmos DB or if it's from the client side.
- Log the diagnostics string in the V2 SDK or diagnostics in V3 SDK from the point operation responses.
- Log the SQL Query Metrics from all the query responses
- Follow the setup for SDK logging

Take a look at the Common issues and workarounds section in this article.

Check the GitHub issues section that's actively monitored. Check to see if any similar issue with a workaround is already filed. If you didn't find a solution, then file a GitHub issue. You can open a support tick for urgent issues.

Common issues and workarounds

General suggestions

- Run your app in the same Azure region as your Azure Cosmos DB account, whenever possible.
- You may run into connectivity/availability issues due to lack of resources on your client machine. We recommend monitoring your CPU utilization on nodes running the Azure Cosmos DB client, and scaling up/out if they're running at high load.

Check the portal metrics

Checking the portal metrics will help determine if it's a client-side issue or if there is an issue with the service. For example, if the metrics contain a high rate of rate-limited requests (HTTP status code 429) which means the request is getting throttled then check the Request rate too large section.

Common error status codes

STATUS CODE	DESCRIPTION
400	Bad request (Depends on the error message)
401	Not authorized
404	Resource is not found
408	Request timed out
409	Conflict failure is when the ID provided for a resource on a write operation has been taken by an existing resource. Use another ID for the resource to resolve this issue as ID must be unique within all documents with the same partition key value.
410	Gone exceptions (Transient failure that should not violate SLA)
412	Precondition failure is where the operation specified an eTag that is different from the version available at the server. It's optimistic concurrency error. Retry the request after reading the latest version of the resource and updating the eTag on the request.
413	Request Entity Too Large
429	Too many requests
449	Transient error that only occurs on write operations, and is safe to retry
500	The operation failed due to an unexpected service error. Contact support. See Filing an Azure support issue.
503	Service unavailable

Azure SNAT (PAT) port exhaustion

If your app is deployed on Azure Virtual Machines without a public IP address, by default Azure SNAT ports establish connections to any endpoint outside of your VM. The number of connections allowed from the VM to the Azure Cosmos DB endpoint is limited by the Azure SNAT configuration. This situation can lead to connection throttling, connection closure, or the above mentioned Request timeouts.

Azure SNAT ports are used only when your VM has a private IP address is connecting to a public IP address. There are two workarounds to avoid Azure SNAT limitation (provided you already are using a single client instance across the entire application):

- Add your Azure Cosmos DB service endpoint to the subnet of your Azure Virtual Machines virtual network. For more information, see Azure Virtual Network service endpoints.

  When the service endpoint is enabled, the requests are no longer sent from a public IP to Azure Cosmos DB. Instead, the virtual network and subnet identity are sent. This change might result in firewall drops if only public IPs are allowed. If you use a firewall, when you enable the service endpoint, add a subnet to the firewall by using Virtual Network ACLs.

- Assign a public IP to your Azure VM.

High network latency

High network latency can be identified by using the diagnostics string in the V2 SDK or diagnostics in V3 SDK.

If no timeouts are present and the diagnostics show single requests where the high latency is evident on the difference between `ResponseTime` and `RequestStartTime`, like so (>300 milliseconds in this example):

```
RequestStartTime: 2020-03-09T22:44:49.5373624Z, RequestEndTime: 2020-03-09T22:44:49.9279906Z,  Number of
regions attempted:1
ResponseTime: 2020-03-09T22:44:49.9279906Z, StoreResult: StorePhysicalAddress: rntbd://..., ...
```

This latency can have multiple causes:

- Your application is not running in the same region as your Azure Cosmos DB account.
- Your PreferredLocations or ApplicationRegion configuration is incorrect and is trying to connect to a different region to where your application is currently running on.
- There might be a bottleneck on the Network interface because of high traffic. If the application is running on Azure Virtual Machines, there are possible workarounds:
  - Consider using a Virtual Machine with Accelerated Networking enabled.
  - Enable Accelerated Networking on an existing Virtual Machine.
  - Consider using a higher end Virtual Machine.

Common query issues

The query metrics will help determine where the query is spending most of the time. From the query metrics, you can see how much of it is being spent on the back-end vs the client. Learn more about troubleshooting query performance.

- If the back-end query returns quickly, and spends a large time on the client check the load on the machine. It's likely that there are not enough resource and the SDK is waiting for resources to be available to handle the response.

- If the back-end query is slow, try optimizing the query and looking at the current indexing policy

> **NOTE**
>
> For improved performance, we recommend Windows 64-bit host processing. The SQL SDK includes a native ServiceInterop.dll to parse and optimize queries locally. ServiceInterop.dll is supported only on the Windows x64 platform. For Linux and other unsupported platforms where ServiceInterop.dll isn't available, an additional network call will be made to the gateway to get the optimized query.

If you encounter the following error:
`Unable to load DLL 'Microsoft.Azure.Cosmos.ServiceInterop.dll' or one of its dependencies:` and are using Windows, you should upgrade to the latest Windows version.

Diagnose and troubleshoot Azure Cosmos DB "Request header too large" message

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The "Request header too large" message is thrown with an HTTP error code 400. This error occurs if the size of the request header has grown so large that it exceeds the maximum-allowed size. We recommend that you use the latest version of the SDK. Use at least version 3.x or 2.x, because these versions add header size tracing to the exception message.

Troubleshooting steps

The "Request header too large" message occurs if the session or the continuation token is too large. The following sections describe the cause of the issue and its solution in each category.

Session token is too large

Cause:

A 400 bad request most likely occurs because the session token is too large. If the following statements are true, the session token is too large:

- The error occurs on point operations like create, read, and update where there isn't a continuation token.
- The exception started without making any changes to the application. The session token grows as the number of partitions increases in the container. The number of partitions increases as the amount of data increases or if the throughput is increased.

Temporary mitigation:

Restart your client application to reset all the session tokens. Eventually, the session token will grow back to the previous size that caused the issue. To avoid this issue completely, use the solution in the next section.

Solution:

1. Follow the guidance in the .NET v3 or .NET v2 performance tips articles. Convert the application to use the direct connection mode with the Transmission Control Protocol (TCP). The direct connection mode with the TCP protocol doesn't have the header size restriction like the HTTP protocol, so it avoids this issue. Make sure to use the latest version of the SDK, which has a fix for query operations when the service interop isn't available.
2. If the direct connection mode with the TCP protocol isn't an option for your workload, mitigate it by changing the client consistency level. The session token is only used for session consistency, which is the default consistency level for Azure Cosmos DB. Other consistency levels don't use the session token.

Continuation token is too large

Cause:

The 400 bad request occurs on query operations where the continuation token is used if the continuation token has grown too large or if different queries have different continuation token sizes.

Solution:

1. Follow the guidance in the .NET v3 or .NET v2 performance tips articles. Convert the application to use the direct connection mode with the TCP protocol. The direct connection mode with the TCP protocol doesn't have the header size restriction like the HTTP protocol, so it avoids this issue.
2. If the direct connection mode with the TCP protocol isn't an option for your workload, set the `ResponseContinuationTokenLimitInKb` option. You can find this option in `FeedOptions` in v2 or

`QueryRequestOptions` in v3.

Diagnose and troubleshoot Azure Cosmos DB .NET SDK request timeout exceptions

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

The HTTP 408 error occurs if the SDK was unable to complete the request before the timeout limit occurred.

Customize the timeout on the Azure Cosmos DB .NET SDK

The SDK has two distinct alternatives to control timeouts, each with a different scope.

RequestTimeout

The `CosmosClientOptions.RequestTimeout` (or `ConnectionPolicy.RequestTimeout` for SDK v2) configuration allows you to set a timeout that affects each individual network request. An operation started by a user can span multiple network requests (for example, there could be throttling). This configuration would apply for each network request on the retry. This timeout isn't an end-to-end operation request timeout.

CancellationToken

All the async operations in the SDK have an optional CancellationToken parameter. This CancellationToken parameter is used throughout the entire operation, across all network requests. In between network requests, the cancellation token might be checked and an operation canceled if the related token is expired. The cancellation token should be used to define an approximate expected timeout on the operation scope.

> **NOTE**
>
> The `CancellationToken` parameter is a mechanism where the library will check the cancellation when it won't cause an invalid state. The operation might not cancel exactly when the time defined in the cancellation is up. Instead, after the time is up, it cancels when it's safe to do so.

Troubleshooting steps

The following list contains known causes and solutions for request timeout exceptions.

High CPU utilization

High CPU utilization is the most common case. For optimal latency, CPU usage should be roughly 40 percent. Use 10 seconds as the interval to monitor maximum (not average) CPU utilization. CPU spikes are more common with cross-partition queries where it might do multiple connections for a single query.

Solution:

The client application that uses the SDK should be scaled up or out.

Socket or port availability might be low

When running in Azure, clients using the .NET SDK can hit Azure SNAT (PAT) port exhaustion.

Solution 1:

If you're running on Azure VMs, follow the SNAT port exhaustion guide.

Solution 2:

If you're running on Azure App Service, follow the connection errors troubleshooting guide and use App Service diagnostics.

Solution 3:

If you're running on Azure Functions, verify you're following the Azure Functions recommendation of maintaining singleton or static clients for all of the involved services (including Azure Cosmos DB). Check the service limits based on the type and size of your Function App hosting.

Solution 4:

If you use an HTTP proxy, make sure it can support the number of connections configured in the SDK `ConnectionPolicy`. Otherwise, you'll face connection issues.

Create multiple client instances

Creating multiple client instances might lead to connection contention and timeout issues.

Solution:

Follow the performance tips, and use a single CosmosClient instance across an entire process.

Hot partition key

Azure Cosmos DB distributes the overall provisioned throughput evenly across physical partitions. When there's a hot partition, one or more logical partition keys on a physical partition are consuming all the physical partition's Request Units per second (RU/s). At the same time, the RU/s on other physical partitions are going unused. As a symptom, the total RU/s consumed will be less than the overall provisioned RU/s at the database or container, but you'll still see throttling (429s) on the requests against the hot logical partition key. Use the Normalized RU Consumption metric to see if the workload is encountering a hot partition.

Solution:

Choose a good partition key that evenly distributes request volume and storage. Learn how to change your partition key.

High degree of concurrency

The application is doing a high level of concurrency, which can lead to contention on the channel.

Solution:

The client application that uses the SDK should be scaled up or out.

Large requests or responses

Large requests or responses can lead to head-of-line blocking on the channel and exacerbate contention, even with a relatively low degree of concurrency.

Solution:

The client application that uses the SDK should be scaled up or out.

Failure rate is within the Azure Cosmos DB SLA

The application should be able to handle transient failures and retry when necessary. Any 408 exceptions aren't retried because on create paths it's impossible to know if the service created the item or not. Sending the same item again for create will cause a conflict exception. User applications business logic might have custom logic to handle conflicts, which would break from the ambiguity of an existing item versus conflict from a create retry.

Failure rate violates the Azure Cosmos DB SLA

Diagnose and troubleshoot Azure Cosmos DB service unavailable exceptions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The SDK wasn't able to connect to Azure Cosmos DB.

Troubleshooting steps

The following list contains known causes and solutions for service unavailable exceptions.

The required ports are being blocked

Verify that all the required ports are enabled.

Client-side transient connectivity issues

Service unavailable exceptions can surface when there are transient connectivity problems that are causing timeouts. Typically, the stack trace related to this scenario will contain a `TransportException` error. For example:

```
TransportException: A client transport error occurred: The request timed out while waiting for a server
response.
(Time: xxx, activity ID: xxx, error code: ReceiveTimeout [0x0010], base error: HRESULT 0x80131500
```

Follow the request timeout troubleshooting steps to resolve it.

Service outage

Check the Azure status to see if there's an ongoing issue.

Next steps

- Diagnose and troubleshoot issues when you use the Azure Cosmos DB .NET SDK.

Troubleshoot issues when you use Azure Cosmos DB Java SDK v4 with SQL API accounts

12/4/2020 • 9 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> This article covers troubleshooting for Azure Cosmos DB Java SDK v4 only. Please see the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, and performance tips for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

This article covers common issues, workarounds, diagnostic steps, and tools when you use Azure Cosmos DB Java SDK v4 with Azure Cosmos DB SQL API accounts. Azure Cosmos DB Java SDK v4 provides client-side logical representation to access the Azure Cosmos DB SQL API. This article describes tools and approaches to help you if you run into any issues.

Start with this list:

- Take a look at the Common issues and workarounds section in this article.
- Look at the Java SDK in the Azure Cosmos DB central repo, which is available open source on GitHub. It has an issues section that's actively monitored. Check to see if any similar issue with a workaround is already filed. One helpful tip is to filter issues by the *cosmos:v4-item* tag.
- Review the performance tips for Azure Cosmos DB Java SDK v4, and follow the suggested practices.
- Read the rest of this article, if you didn't find a solution. Then file a GitHub issue. If there is an option to add tags to your GitHub issue, add a *cosmos:v4-item* tag.

Common issues and workarounds

Network issues, Netty read timeout failure, low throughput, high latency

General suggestions

For best performance:

- Make sure the app is running on the same region as your Azure Cosmos DB account.
- Check the CPU usage on the host where the app is running. If CPU usage is 50 percent or more, run your app on a host with a higher configuration. Or you can distribute the load on more machines.
  - If you are running your application on Azure Kubernetes Service, you can use Azure Monitor to monitor CPU utilization.

Connection throttling

Connection throttling can happen because of either a connection limit on a host machine or Azure SNAT (PAT) port exhaustion.

Connection limit on a host machine

Some Linux systems, such as Red Hat, have an upper limit on the total number of open files. Sockets in Linux are implemented as files, so this number limits the total number of connections, too. Run the following command.

```
ulimit -a
```

The number of max allowed open files, which are identified as "nofile," needs to be at least double your connection pool size. For more information, see the Azure Cosmos DB Java SDK v4 performance tips.

Azure SNAT (PAT) port exhaustion

If your app is deployed on Azure Virtual Machines without a public IP address, by default Azure SNAT ports establish connections to any endpoint outside of your VM. The number of connections allowed from the VM to the Azure Cosmos DB endpoint is limited by the Azure SNAT configuration.

Azure SNAT ports are used only when your VM has a private IP address and a process from the VM tries to connect to a public IP address. There are two workarounds to avoid Azure SNAT limitation:

- Add your Azure Cosmos DB service endpoint to the subnet of your Azure Virtual Machines virtual network. For more information, see Azure Virtual Network service endpoints.

  When the service endpoint is enabled, the requests are no longer sent from a public IP to Azure Cosmos DB. Instead, the virtual network and subnet identity are sent. This change might result in firewall drops if only public IPs are allowed. If you use a firewall, when you enable the service endpoint, add a subnet to the firewall by using Virtual Network ACLs.

- Assign a public IP to your Azure VM.

Can't reach the Service - firewall

`ConnectTimeoutException` indicates that the SDK cannot reach the service. You may get a failure similar to the following when using the direct mode:

```
GoneException{error=null, resourceAddress='https://cdb-ms-prod-westus-
fd4.documents.azure.com:14940/apps/e41242a5-2d71-5acb-2e00-5e5f744b12de/services/d8aa21a5-340b-21d4-b1a2-
4a5333e7ed8a/partitions/ed028254-b613-4c2a-bf3c-14bd5eb64500/replicas/131298754052060051p//',
statusCode=410, message=Message: The requested resource is no longer available at the server.,
getCauseInfo=[class: class io.netty.channel.ConnectTimeoutException, message: connection timed out: cdb-ms-
prod-westus-fd4.documents.azure.com/101.13.12.5:14940]
```

If you have a firewall running on your app machine, open port range 10,000 to 20,000 which are used by the direct mode. Also follow the Connection limit on a host machine.

HTTP proxy

If you use an HTTP proxy, make sure it can support the number of connections configured in the SDK `ConnectionPolicy`. Otherwise, you face connection issues.

Invalid coding pattern: Blocking Netty IO thread

The SDK uses the Netty IO library to communicate with Azure Cosmos DB. The SDK has an Async API and uses non-blocking IO APIs of Netty. The SDK's IO work is performed on IO Netty threads. The number of IO Netty threads is configured to be the same as the number of CPU cores of the app machine.

The Netty IO threads are meant to be used only for non-blocking Netty IO work. The SDK returns the API invocation result on one of the Netty IO threads to the app's code. If the app performs a long-lasting operation after it receives results on the Netty thread, the SDK might not have enough IO threads to perform its internal IO work. Such app coding might result in low throughput, high latency, and `io.netty.handler.timeout.ReadTimeoutException` failures. The workaround is to switch the thread when you know the operation takes time.

For example, take a look at the following code snippet which adds items to a container (look here for guidance on setting up the database and container.) You might perform long-lasting work that takes more than a few milliseconds on the Netty thread. If so, you eventually can get into a state where no Netty IO thread is present to process IO work. As a result, you get a ReadTimeoutException failure.

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
//Bad code with read timeout exception

int requestTimeoutInSeconds = 10;

/* ... */

AtomicInteger failureCount = new AtomicInteger();
// Max number of concurrent item inserts is # CPU cores + 1
Flux<Family> familyPub =
        Flux.just(Families.getAndersenFamilyItem(), Families.getAndersenFamilyItem(),
Families.getJohnsonFamilyItem());
familyPub.flatMap(family -> {
    return container.createItem(family);
}).flatMap(r -> {
    try {
        // Time-consuming work is, for example,
        // writing to a file, computationally heavy work, or just sleep.
        // Basically, it's anything that takes more than a few milliseconds.
        // Doing such operations on the IO Netty thread
        // without a proper scheduler will cause problems.
        // The subscriber will get a ReadTimeoutException failure.
        TimeUnit.SECONDS.sleep(2 * requestTimeoutInSeconds);
    } catch (Exception e) {
    }
    return Mono.empty();
}).doOnError(Exception.class, exception -> {
    failureCount.incrementAndGet();
}).blockLast();
assert(failureCount.get() > 0);
```

The workaround is to change the thread on which you perform work that takes time. Define a singleton instance of the scheduler for your app.

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
// Have a singleton instance of an executor and a scheduler.
ExecutorService ex  = Executors.newFixedThreadPool(30);
Scheduler customScheduler = Schedulers.fromExecutor(ex);
```

You might need to do work that takes time, for example, computationally heavy work or blocking IO. In this case, switch the thread to a worker provided by your `customScheduler` by using the `.publishOn(customScheduler)` API.

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
container.createItem(family)
        .publishOn(customScheduler) // Switches the thread.
        .subscribe(
                // ...
        );
```

By using `publishOn(customScheduler)`, you release the Netty IO thread and switch to your own custom thread provided by the custom scheduler. This modification solves the problem. You won't get a `io.netty.handler.timeout.ReadTimeoutException` failure anymore.

Request rate too large

This failure is a server-side failure. It indicates that you consumed your provisioned throughput. Retry later. If you get this failure often, consider an increase in the collection throughput.

- **Implement backoff at getRetryAfterInMilliseconds intervals**

  During performance testing, you should increase load until a small rate of requests get throttled. If throttled, the client application should backoff for the server-specified retry interval. Respecting the backoff ensures that you spend minimal amount of time waiting between retries.

Failure connecting to Azure Cosmos DB Emulator

The Azure Cosmos DB Emulator HTTPS certificate is self-signed. For the SDK to work with the emulator, import the emulator certificate to a Java TrustStore. For more information, see Export Azure Cosmos DB Emulator certificates.

Dependency Conflict Issues

The Azure Cosmos DB Java SDK pulls in a number of dependencies; generally speaking, if your project dependency tree includes an older version of an artifact that Azure Cosmos DB Java SDK depends on, this may result in unexpected errors being generated when you run your application. If you are debugging why your application unexpectedly throws an exception, it is a good idea to double-check that your dependency tree is not accidentally pulling in an older version of one or more of the Azure Cosmos DB Java SDK dependencies.

The workaround for such an issue is to identify which of your project dependencies brings in the old version and exclude the transitive dependency on that older version, and allow Azure Cosmos DB Java SDK to bring in the newer version.

To identify which of your project dependencies brings in an older version of something that Azure Cosmos DB Java SDK depends on, run the following command against your project pom.xml file:

```
mvn dependency:tree
```

For more information, see the maven dependency tree guide.

Once you know which dependency of your project depends on an older version, you can modify the dependency on that lib in your pom file and exclude the transitive dependency, following the example below (which assumes that *reactor-core* is the outdated dependency):

```
<dependency>
  <groupId>${groupid-of-lib-which-brings-in-reactor}</groupId>
  <artifactId>${artifactId-of-lib-which-brings-in-reactor}</artifactId>
  <version>${version-of-lib-which-brings-in-reactor}</version>
  <exclusions>
    <exclusion>
      <groupId>io.projectreactor</groupId>
      <artifactId>reactor-core</artifactId>
    </exclusion>
  </exclusions>
</dependency>
```

For more information, see the exclude transitive dependency guide.

Enable client SDK logging

Azure Cosmos DB Java SDK v4 uses SLF4j as the logging facade that supports logging into popular logging frameworks such as log4j and logback.

For example, if you want to use log4j as the logging framework, add the following libs in your Java classpath.

```
<dependency>
  <groupId>org.slf4j</groupId>
  <artifactId>slf4j-log4j12</artifactId>
  <version>${slf4j.version}</version>
</dependency>
<dependency>
  <groupId>log4j</groupId>
  <artifactId>log4j</artifactId>
  <version>${log4j.version}</version>
</dependency>
```

Also add a log4j config.

```
# this is a sample log4j configuration

# Set root logger level to INFO and its only appender to A1.
log4j.rootLogger=INFO, A1

log4j.category.com.azure.cosmos=INFO
#log4j.category.io.netty=OFF
#log4j.category.io.projectreactor=OFF
# A1 is set to be a ConsoleAppender.
log4j.appender.A1=org.apache.log4j.ConsoleAppender

# A1 uses PatternLayout.
log4j.appender.A1.layout=org.apache.log4j.PatternLayout
log4j.appender.A1.layout.ConversionPattern=%d %5X{pid} [%t] %-5p %c - %m%n
```

For more information, see the sfl4j logging manual.

OS network statistics

Run the netstat command to get a sense of how many connections are in states such as `ESTABLISHED` and `CLOSE_WAIT`.

On Linux, you can run the following command.

```
netstat -nap
```

On Windows, you can run the same command with different argument flags:

```
netstat -abn
```

Filter the result to only connections to the Azure Cosmos DB endpoint.

The number of connections to the Azure Cosmos DB endpoint in the `ESTABLISHED` state can't be greater than your configured connection pool size.

Many connections to the Azure Cosmos DB endpoint might be in the `CLOSE_WAIT` state. There might be more than 1,000. A number that high indicates that connections are established and torn down quickly. This situation potentially causes problems. For more information, see the Common issues and workarounds section.

Diagnose and troubleshoot Azure Cosmos DB Java v4 SDK request timeout exceptions

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

The HTTP 408 error occurs if the SDK was unable to complete the request before the timeout limit occurred.

Troubleshooting steps

The following list contains known causes and solutions for request timeout exceptions.

Existing issues

If you are seeing requests getting stuck for longer duration or timing out more frequently, please upgrade the Java v4 SDK to the latest version. NOTE: We strongly recommend to use the version 4.7.0 and above. Checkout the Java v4 SDK release notes for more details.

High CPU utilization

High CPU utilization is the most common case. For optimal latency, CPU usage should be roughly 40 percent. Use 10 seconds as the interval to monitor maximum (not average) CPU utilization. CPU spikes are more common with cross-partition queries where it might do multiple connections for a single query.

Solution:

The client application that uses the SDK should be scaled up or out.

Connection throttling

Connection throttling can happen because of either a connection limit on a host machine or Azure SNAT (PAT) port exhaustion.

Connection limit on a host machine

Some Linux systems, such as Red Hat, have an upper limit on the total number of open files. Sockets in Linux are implemented as files, so this number limits the total number of connections, too. Run the following command.

```
ulimit -a
```

Solution:

The number of max allowed open files, which are identified as "nofile," needs to be at least 10,000 or more. For more information, see the Azure Cosmos DB Java SDK v4 performance tips.

Socket or port availability might be low

When running in Azure, clients using the Java SDK can hit Azure SNAT (PAT) port exhaustion.

Solution 1:

If you're running on Azure VMs, follow the SNAT port exhaustion guide.

Solution 2:

If you're running on Azure App Service, follow the connection errors troubleshooting guide and use App Service diagnostics.

Solution 3:

If you're running on Azure Functions, verify you're following the Azure Functions recommendation of maintaining

singleton or static clients for all of the involved services (including Azure Cosmos DB). Check the service limits based on the type and size of your Function App hosting.

Solution 4:

If you use an HTTP proxy, make sure it can support the number of connections configured in the SDK `GatewayConnectionConfig`. Otherwise, you'll face connection issues.

Create multiple client instances

Creating multiple client instances might lead to connection contention and timeout issues.

Solution 1:

Follow the performance tips, and use a single CosmosClient instance across an entire application.

Solution 2:

If singleton CosmosClient is not possible to have in an application, we recommend using connection sharing across multiple Cosmos Clients through this API `connectionSharingAcrossClientsEnabled(true)` in CosmosClient. When you have multiple instances of Cosmos Client in the same JVM interacting to multiple Cosmos accounts, enabling this allows connection sharing in Direct mode if possible between instances of Cosmos Client. Please note, when setting this option, the connection configuration (e.g., socket timeout config, idle timeout config) of the first instantiated client will be used for all other client instances.

Hot partition key

Azure Cosmos DB distributes the overall provisioned throughput evenly across physical partitions. When there's a hot partition, one or more logical partition keys on a physical partition are consuming all the physical partition's Request Units per second (RU/s). At the same time, the RU/s on other physical partitions are going unused. As a symptom, the total RU/s consumed will be less than the overall provisioned RU/s at the database or container, but you'll still see throttling (429s) on the requests against the hot logical partition key. Use the Normalized RU Consumption metric to see if the workload is encountering a hot partition.

Solution:

Choose a good partition key that evenly distributes request volume and storage. Learn how to change your partition key.

High degree of concurrency

The application is doing a high level of concurrency, which can lead to contention on the channel.

Solution:

The client application that uses the SDK should be scaled up or out.

Large requests or responses

Large requests or responses can lead to head-of-line blocking on the channel and exacerbate contention, even with a relatively low degree of concurrency.

Solution:

The client application that uses the SDK should be scaled up or out.

Failure rate is within the Azure Cosmos DB SLA

The application should be able to handle transient failures and retry when necessary. Any 408 exceptions aren't retried because on create paths it's impossible to know if the service created the item or not. Sending the same item again for create will cause a conflict exception. User applications business logic might have custom logic to handle conflicts, which would break from the ambiguity of an existing item versus conflict from a create retry.

Failure rate violates the Azure Cosmos DB SLA

Contact Azure Support.

Diagnose and troubleshoot Azure Cosmos DB Java v4 SDK service unavailable exceptions

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

The Java v4 SDK wasn't able to connect to Azure Cosmos DB.

Troubleshooting steps

The following list contains known causes and solutions for service unavailable exceptions.

The required ports are being blocked

Verify that all the required ports are enabled.

Client-side transient connectivity issues

Service unavailable exceptions can surface when there are transient connectivity problems that are causing timeouts. Typically, the stack trace related to this scenario will contain a `ServiceUnavailableException` error with diagnostic details. For example:

```
Exception in thread "main" ServiceUnavailableException{userAgent=azsdk-java-cosmos/4.6.0 Linux/4.15.0-1096-azure JRE/11.0.8, error=null, resourceAddress='null', requestUri='null', statusCode=503, message=Service is currently unavailable, please retry after a while. If this problem persists please contact support.: Message: "" {"diagnostics"}
```

Follow the request timeout troubleshooting steps to resolve it.

Service outage

Check the Azure status to see if there's an ongoing issue.

Next steps

- Diagnose and troubleshoot issues when you use the Azure Cosmos DB Java v4 SDK.
- Learn about performance guidelines for Java v4 SDK.

Troubleshoot issues when you use the Azure Cosmos DB Async Java SDK v2 with SQL API accounts

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> This is *not* the latest Java SDK for Azure Cosmos DB! You should upgrade your project to Azure Cosmos DB Java SDK v4 and then read the Azure Cosmos DB Java SDK v4 troubleshooting guide. Follow the instructions in the Migrate to Azure Cosmos DB Java SDK v4 guide and Reactor vs RxJava guide to upgrade.
>
> This article covers troubleshooting for Azure Cosmos DB Async Java SDK v2 only. See the Azure Cosmos DB Async Java SDK v2 Release Notes, Maven repository and performance tips for more information.

This article covers common issues, workarounds, diagnostic steps, and tools when you use the Java Async SDK with Azure Cosmos DB SQL API accounts. The Java Async SDK provides client-side logical representation to access the Azure Cosmos DB SQL API. This article describes tools and approaches to help you if you run into any issues.

Start with this list:

- Take a look at the Common issues and workarounds section in this article.
- Look at the SDK, which is available open source on GitHub. It has an issues section that's actively monitored. Check to see if any similar issue with a workaround is already filed.
- Review the performance tips, and follow the suggested practices.
- Read the rest of this article, if you didn't find a solution. Then file a GitHub issue.

Common issues and workarounds

Network issues, Netty read timeout failure, low throughput, high latency

General suggestions

- Make sure the app is running on the same region as your Azure Cosmos DB account.
- Check the CPU usage on the host where the app is running. If CPU usage is 90 percent or more, run your app on a host with a higher configuration. Or you can distribute the load on more machines.

Connection throttling

Connection throttling can happen because of either a connection limit on a host machine or Azure SNAT (PAT) port exhaustion.

Connection limit on a host machine

Some Linux systems, such as Red Hat, have an upper limit on the total number of open files. Sockets in Linux are implemented as files, so this number limits the total number of connections, too. Run the following command.

```
ulimit -a
```

The number of max allowed open files, which are identified as "nofile," needs to be at least double your connection pool size. For more information, see Performance tips.

Azure SNAT (PAT) port exhaustion

If your app is deployed on Azure Virtual Machines without a public IP address, by default Azure SNAT ports

establish connections to any endpoint outside of your VM. The number of connections allowed from the VM to the Azure Cosmos DB endpoint is limited by the Azure SNAT configuration.

Azure SNAT ports are used only when your VM has a private IP address and a process from the VM tries to connect to a public IP address. There are two workarounds to avoid Azure SNAT limitation:

- Add your Azure Cosmos DB service endpoint to the subnet of your Azure Virtual Machines virtual network. For more information, see Azure Virtual Network service endpoints.

  When the service endpoint is enabled, the requests are no longer sent from a public IP to Azure Cosmos DB. Instead, the virtual network and subnet identity are sent. This change might result in firewall drops if only public IPs are allowed. If you use a firewall, when you enable the service endpoint, add a subnet to the firewall by using Virtual Network ACLs.

- Assign a public IP to your Azure VM.

Can't reach the Service - firewall

`ConnectTimeoutException` indicates that the SDK cannot reach the service. You may get a failure similar to the following when using the direct mode:

```
GoneException{error=null, resourceAddress='https://cdb-ms-prod-westus-
fd4.documents.azure.com:14940/apps/e41242a5-2d71-5acb-2e00-5e5f744b12de/services/d8aa21a5-340b-21d4-b1a2-
4a5333e7ed8a/partitions/ed028254-b613-4c2a-bf3c-14bd5eb64500/replicas/131298754052060051p//', statusCode=410,
message=Message: The requested resource is no longer available at the server., getCauseInfo=[class: class
io.netty.channel.ConnectTimeoutException, message: connection timed out: cdb-ms-prod-westus-
fd4.documents.azure.com/101.13.12.5:14940]
```

If you have a firewall running on your app machine, open port range 10,000 to 20,000 which are used by the direct mode. Also follow the Connection limit on a host machine.

HTTP proxy

If you use an HTTP proxy, make sure it can support the number of connections configured in the SDK `ConnectionPolicy`. Otherwise, you face connection issues.

Invalid coding pattern: Blocking Netty IO thread

The SDK uses the Netty IO library to communicate with Azure Cosmos DB. The SDK has Async APIs and uses non-blocking IO APIs of Netty. The SDK's IO work is performed on IO Netty threads. The number of IO Netty threads is configured to be the same as the number of CPU cores of the app machine.

The Netty IO threads are meant to be used only for non-blocking Netty IO work. The SDK returns the API invocation result on one of the Netty IO threads to the app's code. If the app performs a long-lasting operation after it receives results on the Netty thread, the SDK might not have enough IO threads to perform its internal IO work. Such app coding might result in low throughput, high latency, and `io.netty.handler.timeout.ReadTimeoutException` failures. The workaround is to switch the thread when you know the operation takes time.

For example, take a look at the following code snippet. You might perform long-lasting work that takes more than a few milliseconds on the Netty thread. If so, you eventually can get into a state where no Netty IO thread is present to process IO work. As a result, you get a ReadTimeoutException failure.

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
@Test
public void badCodeWithReadTimeoutException() throws Exception {
    int requestTimeoutInSeconds = 10;

    ConnectionPolicy policy = new ConnectionPolicy();
    policy.setRequestTimeoutInMillis(requestTimeoutInSeconds * 1000);

    AsyncDocumentClient testClient = new AsyncDocumentClient.Builder()
            .withServiceEndpoint(TestConfigurations.HOST)
            .withMasterKeyOrResourceToken(TestConfigurations.MASTER_KEY)
            .withConnectionPolicy(policy)
            .build();

    int numberOfCpuCores = Runtime.getRuntime().availableProcessors();
    int numberOfConcurrentWork = numberOfCpuCores + 1;
    CountDownLatch latch = new CountDownLatch(numberOfConcurrentWork);
    AtomicInteger failureCount = new AtomicInteger();

    for (int i = 0; i < numberOfConcurrentWork; i++) {
        Document docDefinition = getDocumentDefinition();
        Observable<ResourceResponse<Document>> createObservable = testClient
                .createDocument(getCollectionLink(), docDefinition, null, false);
        createObservable.subscribe(r -> {
                    try {
                        // Time-consuming work is, for example,
                        // writing to a file, computationally heavy work, or just sleep.
                        // Basically, it's anything that takes more than a few milliseconds.
                        // Doing such operations on the IO Netty thread
                        // without a proper scheduler will cause problems.
                        // The subscriber will get a ReadTimeoutException failure.
                        TimeUnit.SECONDS.sleep(2 * requestTimeoutInSeconds);
                    } catch (Exception e) {
                    }
                },

                exception -> {
                    //It will be io.netty.handler.timeout.ReadTimeoutException.
                    exception.printStackTrace();
                    failureCount.incrementAndGet();
                    latch.countDown();
                },
                () -> {
                    latch.countDown();
                });
    }

    latch.await();
    assertThat(failureCount.get()).isGreaterThan(0);
}
```

The workaround is to change the thread on which you perform work that takes time. Define a singleton instance of the scheduler for your app.

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
// Have a singleton instance of an executor and a scheduler.
ExecutorService ex  = Executors.newFixedThreadPool(30);
Scheduler customScheduler = rx.schedulers.Schedulers.from(ex);
```

You might need to do work that takes time, for example, computationally heavy work or blocking IO. In this case, switch the thread to a worker provided by your `customScheduler` by using the `.observeOn(customScheduler)` API.

Async Java SDK V2 (Maven com.microsoft.azure::azure-cosmosdb)

```
Observable<ResourceResponse<Document>> createObservable = client
        .createDocument(getCollectionLink(), docDefinition, null, false);

createObservable
        .observeOn(customScheduler) // Switches the thread.
        .subscribe(
            // ...
        );
```

By using `observeOn(customScheduler)`, you release the Netty IO thread and switch to your own custom thread provided by the custom scheduler. This modification solves the problem. You won't get a `io.netty.handler.timeout.ReadTimeoutException` failure anymore.

Connection pool exhausted issue

`PoolExhaustedException` is a client-side failure. This failure indicates that your app workload is higher than what the SDK connection pool can serve. Increase the connection pool size or distribute the load on multiple apps.

Request rate too large

This failure is a server-side failure. It indicates that you consumed your provisioned throughput. Retry later. If you get this failure often, consider an increase in the collection throughput.

Failure connecting to Azure Cosmos DB Emulator

The Azure Cosmos DB Emulator HTTPS certificate is self-signed. For the SDK to work with the emulator, import the emulator certificate to a Java TrustStore. For more information, see Export Azure Cosmos DB Emulator certificates.

Dependency Conflict Issues

```
Exception in thread "main" java.lang.NoSuchMethodError: rx.Observable.toSingle()Lrx/Single;
```

The above exception suggests you have a dependency on an older version of RxJava lib (e.g., 1.2.2). Our SDK relies on RxJava 1.3.8 which has APIs not available in earlier version of RxJava.

The workaround for such issues is to identify which other dependency brings in RxJava-1.2.2 and exclude the transitive dependency on RxJava-1.2.2, and allow CosmosDB SDK bring the newer version.

To identify which library brings in RxJava-1.2.2 run the following command next to your project pom.xml file:

```
mvn dependency:tree
```

For more information, see the maven dependency tree guide.

Once you identify RxJava-1.2.2 is transitive dependency of which other dependency of your project, you can modify the dependency on that lib in your pom file and exclude RxJava transitive dependency it:

```
<dependency>
  <groupId>${groupid-of-lib-which-brings-in-rxjava1.2.2}</groupId>
  <artifactId>${artifactId-of-lib-which-brings-in-rxjava1.2.2}</artifactId>
  <version>${version-of-lib-which-brings-in-rxjava1.2.2}</version>
  <exclusions>
    <exclusion>
      <groupId>io.reactivex</groupId>
      <artifactId>rxjava</artifactId>
    </exclusion>
  </exclusions>
</dependency>
```

For more information, see the exclude transitive dependency guide.

Enable client SDK logging

The Java Async SDK uses SLF4j as the logging facade that supports logging into popular logging frameworks such as log4j and logback.

For example, if you want to use log4j as the logging framework, add the following libs in your Java classpath.

```
<dependency>
  <groupId>org.slf4j</groupId>
  <artifactId>slf4j-log4j12</artifactId>
  <version>${slf4j.version}</version>
</dependency>
<dependency>
  <groupId>log4j</groupId>
  <artifactId>log4j</artifactId>
  <version>${log4j.version}</version>
</dependency>
```

Also add a log4j config.

```
# this is a sample log4j configuration

# Set root logger level to DEBUG and its only appender to A1.
log4j.rootLogger=INFO, A1

log4j.category.com.microsoft.azure.cosmosdb=DEBUG
#log4j.category.io.netty=INFO
#log4j.category.io.reactivex=INFO
# A1 is set to be a ConsoleAppender.
log4j.appender.A1=org.apache.log4j.ConsoleAppender

# A1 uses PatternLayout.
log4j.appender.A1.layout=org.apache.log4j.PatternLayout
log4j.appender.A1.layout.ConversionPattern=%d %5X{pid} [%t] %-5p %c - %m%n
```

For more information, see the sfl4j logging manual.

OS network statistics

Run the netstat command to get a sense of how many connections are in states such as `ESTABLISHED` and `CLOSE_WAIT`.

On Linux, you can run the following command.

```
netstat -nap
```

Filter the result to only connections to the Azure Cosmos DB endpoint.

The number of connections to the Azure Cosmos DB endpoint in the `ESTABLISHED` state can't be greater than your configured connection pool size.

Many connections to the Azure Cosmos DB endpoint might be in the `CLOSE_WAIT` state. There might be more than 1,000. A number that high indicates that connections are established and torn down quickly. This situation potentially causes problems. For more information, see the Common issues and workarounds section.

How to configure logging and connectivity with the Azure Functions trigger for Cosmos DB

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes advanced configuration options you can set when using the Azure Functions trigger for Cosmos DB.

Enabling trigger specific logs

The Azure Functions trigger for Cosmos DB uses the Change Feed Processor Library internally, and the library generates a set of health logs that can be used to monitor internal operations for troubleshooting purposes.

The health logs describe how the Azure Functions trigger for Cosmos DB behaves when attempting operations during load-balancing scenarios or initialization.

Enabling logging

To enable logging when using Azure Functions trigger for Cosmos DB, locate the `host.json` file in your Azure Functions project or Azure Functions App and configure the level of required logging. Enable the traces for `Host.Triggers.CosmosDB` as shown in the following sample:

```
{
  "version": "2.0",
  "logging": {
    "fileLoggingMode": "always",
    "logLevel": {
      "Host.Triggers.CosmosDB": "Trace"
    }
  }
}
```

After the Azure Function is deployed with the updated configuration, you will see the Azure Functions trigger for Cosmos DB logs as part of your traces. You can view the logs in your configured logging provider under the *Category* `Host.Triggers.CosmosDB`.

Query the logs

Run the following query to query the logs generated by the Azure Functions trigger for Cosmos DB in Azure Application Insights' Analytics:

```
traces
| where customDimensions.Category == "Host.Triggers.CosmosDB"
```

Configuring the connection policy

There are two connection modes - Direct mode and Gateway mode. To learn more about these connection modes, see the connection modes article. By default, **Gateway** is used to establish all connections on the Azure Functions trigger for Cosmos DB. However, it might not be the best option for performance-driven scenarios.

Changing the connection mode and protocol

There are two key configuration settings available to configure the client connection policy – the **connection mode** and the **connection protocol**. You can change the default connection mode and protocol used by the Azure Functions trigger for Cosmos DB and all the Azure Cosmos DB bindings). To change the default settings, you need to locate the `host.json` file in your Azure Functions project or Azure Functions App and add the following extra setting:

```
{
  "cosmosDB": {
    "connectionMode": "Direct",
    "protocol": "Tcp"
  }
}
```

Where `connectionMode` must have the desired connection mode (Direct or Gateway) and `protocol` the desired connection protocol (Tcp or Https).

If your Azure Functions project is working with Azure Functions V1 runtime, the configuration has a slight name difference, you should use `documentDB` instead of `cosmosDB`:

```
{
  "documentDB": {
    "connectionMode": "Direct",
    "protocol": "Tcp"
  }
}
```

> **NOTE**
> When working with Azure Functions Consumption Plan Hosting plan, each instance has a limit in the amount of Socket Connections that it can maintain. When working with Direct / TCP mode, by design more connections are created and can hit the Consumption Plan limit, in which case you can either use Gateway mode or run your Azure Functions in App Service Mode.

Create multiple Azure Functions triggers for Cosmos DB

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes how you can configure multiple Azure Functions triggers for Cosmos DB to work in parallel and independently react to changes.

Event-based architecture requirements

When building serverless architectures with Azure Functions, it's recommended to create small function sets that work together instead of large long running functions.

As you build event-based serverless flows using the Azure Functions trigger for Cosmos DB, you'll run into the scenario where you want to do multiple things whenever there is a new event in a particular Azure Cosmos container. If actions you want to trigger, are independent from one another, the ideal solution would be to **create one Azure Functions triggers for Cosmos DB per action** you want to do, all listening for changes on the same Azure Cosmos container.

Optimizing containers for multiple Triggers

Given the *requirements* of the Azure Functions trigger for Cosmos DB, we need a second container to store state, also called, the *leases container*. Does this mean that you need a separate leases container for each Azure Function?

Here, you have two options:

- Create **one leases container per Function**: This approach can translate into additional costs, unless you're using a shared throughput database. Remember, that the minimum throughput at the container level is 400 Request Units, and in the case of the leases container, it is only being used to checkpoint the progress and maintain state.

- Have **one lease container and share it** for all your Functions: This second option makes better use of the provisioned Request Units on the container, as it enables multiple Azure Functions to share and use the same provisioned throughput.

The goal of this article is to guide you to accomplish the second option.

Configuring a shared leases container

To configure the shared leases container, the only extra configuration you need to make on your triggers is to add the `LeaseCollectionPrefix` attribute if you are using C# or `leaseCollectionPrefix` attribute if you are using JavaScript. The value of the attribute should be a logical descriptor of what that particular trigger.

For example, if you have three Triggers: one that sends emails, one that does an aggregation to create a materialized view, and one that sends the changes to another storage, for later analysis, you could assign the `LeaseCollectionPrefix` of "emails" to the first one, "materialized" to the second one, and "analytics" to the third one.

The important part is that all three Triggers **can use the same leases container configuration** (account, database, and container name).

A very simple code samples using the `LeaseCollectionPrefix` attribute in C#, would look like this:

```
using Microsoft.Azure.Documents;
using Microsoft.Azure.WebJobs;
using Microsoft.Azure.WebJobs.Host;
using System.Collections.Generic;
using Microsoft.Extensions.Logging;

[FunctionName("SendEmails")]
public static void SendEmails([CosmosDBTrigger(
    databaseName: "ToDoItems",
    collectionName: "Items",
    ConnectionStringSetting = "CosmosDBConnection",
    LeaseCollectionName = "leases",
    LeaseCollectionPrefix = "emails")]IReadOnlyList<Document> documents,
    ILogger log)
{
    ...
}

[FunctionName("MaterializedViews")]
public static void MaterializedViews([CosmosDBTrigger(
    databaseName: "ToDoItems",
    collectionName: "Items",
    ConnectionStringSetting = "CosmosDBConnection",
    LeaseCollectionName = "leases",
    LeaseCollectionPrefix = "materialized")]IReadOnlyList<Document> documents,
    ILogger log)
{
    ...
}
```

And for JavaScript, you can apply the configuration on the `function.json` file, with the `leaseCollectionPrefix` attribute:

```
{
    "type": "cosmosDBTrigger",
    "name": "documents",
    "direction": "in",
    "leaseCollectionName": "leases",
    "connectionStringSetting": "CosmosDBConnection",
    "databaseName": "ToDoItems",
    "collectionName": "Items",
    "leaseCollectionPrefix": "emails"
},
{
    "type": "cosmosDBTrigger",
    "name": "documents",
    "direction": "in",
    "leaseCollectionName": "leases",
    "connectionStringSetting": "CosmosDBConnection",
    "databaseName": "ToDoItems",
    "collectionName": "Items",
    "leaseCollectionPrefix": "materialized"
}
```

NOTE

Always monitor on the Request Units provisioned on your shared leases container. Each Trigger that shares it, will increase the throughput average consumption, so you might need to increase the provisioned throughput as you increase the number of Azure Functions that are using it.

Next steps

Diagnose and troubleshoot issues when using Azure Functions trigger for Cosmos DB

12/4/2020 • 9 minutes to read • Edit Online

APPLIES TO: SQL API

This article covers common issues, workarounds, and diagnostic steps, when you use the Azure Functions trigger for Cosmos DB.

Dependencies

The Azure Functions trigger and bindings for Cosmos DB depend on the extension packages over the base Azure Functions runtime. Always keep these packages updated, as they might include fixes and new features that might address any potential issues you may encounter:

- For Azure Functions V2, see Microsoft.Azure.WebJobs.Extensions.CosmosDB.
- For Azure Functions V1, see Microsoft.Azure.WebJobs.Extensions.DocumentDB.

This article will always refer to Azure Functions V2 whenever the runtime is mentioned, unless explicitly specified.

Consume the Azure Cosmos DB SDK independently

The key functionality of the extension package is to provide support for the Azure Functions trigger and bindings for Cosmos DB. It also includes the Azure Cosmos DB .NET SDK, which is helpful if you want to interact with Azure Cosmos DB programmatically without using the trigger and bindings.

If want to use the Azure Cosmos DB SDK, make sure that you don't add to your project another NuGet package reference. Instead, **let the SDK reference resolve through the Azure Functions' Extension package**. Consume the Azure Cosmos DB SDK separately from the trigger and bindings

Additionally, if you are manually creating your own instance of the Azure Cosmos DB SDK client, you should follow the pattern of having only one instance of the client using a Singleton pattern approach. This process will avoid the potential socket issues in your operations.

Common scenarios and workarounds

Azure Function fails with error message collection doesn't exist

Azure Function fails with error message "Either the source collection 'collection-name' (in database 'database-name') or the lease collection 'collection2-name' (in database 'database2-name') does not exist. Both collections must exist before the listener starts. To automatically create the lease collection, set 'CreateLeaseCollectionIfNotExists' to 'true'"

This means that either one or both of the Azure Cosmos containers required for the trigger to work do not exist or are not reachable to the Azure Function. **The error itself will tell you which Azure Cosmos database and container is the trigger looking for** based on your configuration.

1. Verify the `ConnectionStringSetting` attribute and that it **references a setting that exists in your Azure Function App**. The value on this attribute shouldn't be the Connection String itself, but the name of the Configuration Setting.
2. Verify that the `databaseName` and `collectionName` exist in your Azure Cosmos account. If you are using

automatic value replacement (using `%settingName%` patterns), make sure the name of the setting exists in your Azure Function App.

3. If you don't specify a `LeaseCollectionName/leaseCollectionName`, the default is "leases". Verify that such container exists. Optionally you can set the `CreateLeaseCollectionIfNotExists` attribute in your Trigger to `true` to automatically create it.
4. Verify your Azure Cosmos account's Firewall configuration to see to see that it's not it's not blocking the Azure Function.

Azure Function fails to start with "Shared throughput collection should have a partition key"

The previous versions of the Azure Cosmos DB Extension did not support using a leases container that was created within a shared throughput database. To resolve this issue, update the Microsoft.Azure.WebJobs.Extensions.CosmosDB extension to get the latest version.

Azure Function fails to start with "PartitionKey must be supplied for this operation."

This error means that you are currently using a partitioned lease collection with an old extension dependency. Upgrade to the latest available version. If you are currently running on Azure Functions V1, you will need to upgrade to Azure Functions V2.

Azure Function fails to start with "The lease collection, if partitioned, must have partition key equal to id."

This error means that your current leases container is partitioned, but the partition key path is not `/id`. To resolve this issue, you need to recreate the leases container with `/id` as the partition key.

You see a "Value cannot be null. Parameter name: o" in your Azure Functions logs when you try to Run the Trigger

This issue appears if you are using the Azure portal and you try to select the **Run** button on the screen when inspecting an Azure Function that uses the trigger. The trigger does not require for you to select Run to start, it will automatically start when the Azure Function is deployed. If you want to check the Azure Function's log stream on the Azure portal, just go to your monitored container and insert some new items, you will automatically see the Trigger executing.

My changes take too long to be received

This scenario can have multiple causes and all of them should be checked:

1. Is your Azure Function deployed in the same region as your Azure Cosmos account? For optimal network latency, both the Azure Function and your Azure Cosmos account should be colocated in the same Azure region.
2. Are the changes happening in your Azure Cosmos container continuous or sporadic? If it's the latter, there could be some delay between the changes being stored and the Azure Function picking them up. This is because internally, when the trigger checks for changes in your Azure Cosmos container and finds none pending to be read, it will sleep for a configurable amount of time (5 seconds, by default) before checking for new changes (to avoid high RU consumption). You can configure this sleep time through the `FeedPollDelay/feedPollDelay` setting in the configuration of your trigger (the value is expected to be in milliseconds).
3. Your Azure Cosmos container might be rate-limited.
4. You can use the `PreferredLocations` attribute in your trigger to specify a comma-separated list of Azure regions to define a custom preferred connection order.

Some changes are repeated in my Trigger

The concept of a "change" is an operation on a document. The most common scenarios where events for the same document is received are:

- The account is using Eventual consistency. While consuming the change feed in an Eventual consistency level, there could be duplicate events in-between subsequent change feed read operations (the last event of one read operation appears as the first of the next).
- The document is being updated. The Change Feed can contain multiple operations for the same documents, if that document is receiving updates, it can pick up multiple events (one for each update). One easy way to

distinguish among different operations for the same document is to track the `_lsn` property for each change. If they don't match, these are different changes over the same document.

- If you are identifying documents just by `id`, remember that the unique identifier for a document is the `id` and its partition key (there can be two documents with the same `id` but different partition key).

Some changes are missing in my Trigger

If you find that some of the changes that happened in your Azure Cosmos container are not being picked up by the Azure Function, there is an initial investigation step that needs to take place.

When your Azure Function receives the changes, it often processes them, and could optionally, send the result to another destination. When you are investigating missing changes, make sure you **measure which changes are being received at the ingestion point** (when the Azure Function starts), not on the destination.

If some changes are missing on the destination, this could mean that is some error happening during the Azure Function execution after the changes were received.

In this scenario, the best course of action is to add `try/catch` blocks in your code and inside the loops that might be processing the changes, to detect any failure for a particular subset of items and handle them accordingly (send them to another storage for further analysis or retry).

> **NOTE**
> The Azure Functions trigger for Cosmos DB, by default, won't retry a batch of changes if there was an unhandled exception during your code execution. This means that the reason that the changes did not arrive at the destination is because that you are failing to process them.

If you find that some changes were not received at all by your trigger, the most common scenario is that there is **another Azure Function running**. It could be another Azure Function deployed in Azure or an Azure Function running locally on a developer's machine that has **exactly the same configuration** (same monitored and lease containers), and this Azure Function is stealing a subset of the changes you would expect your Azure Function to process.

Additionally, the scenario can be validated, if you know how many Azure Function App instances you have running. If you inspect your leases container and count the number of lease items within, the distinct values of the `Owner` property in them should be equal to the number of instances of your Function App. If there are more owners than the known Azure Function App instances, it means that these extra owners are the ones "stealing" the changes.

One easy way to work around this situation, is to apply a `LeaseCollectionPrefix/leaseCollectionPrefix` to your Function with a new/different value or, alternatively, test with a new leases container.

Need to restart and reprocess all the items in my container from the beginning

To reprocess all the items in a container from the beginning:

1. Stop your Azure function if it is currently running.
2. Delete the documents in the lease collection (or delete and re-create the lease collection so it is empty)
3. Set the StartFromBeginning CosmosDBTrigger attribute in your function to true.
4. Restart the Azure function. It will now read and process all changes from the beginning.

Setting StartFromBeginning to true will tell the Azure function to start reading changes from the beginning of the history of the collection instead of the current time. This only works when there are no already created leases (that is, documents in the leases collection). Setting this property to true when there are leases already created has no effect; in this scenario, when a function is stopped and restarted, it will begin reading from the last checkpoint, as defined in the leases collection. To reprocess from the beginning, follow the above steps 1-4.

Binding can only be done with IReadOnlyList<Document> or JArray

This error happens if your Azure Functions project (or any referenced project) contains a manual NuGet reference to the Azure Cosmos DB SDK with a different version than the one provided by the Azure Functions Cosmos DB Extension.

To work around this situation, remove the manual NuGet reference that was added and let the Azure Cosmos DB SDK reference resolve through the Azure Functions Cosmos DB Extension package.

Changing Azure Function's polling interval for the detecting changes

As explained earlier for My changes take too long to be received, Azure function will sleep for a configurable amount of time (5 seconds, by default) before checking for new changes (to avoid high RU consumption). You can configure this sleep time through the `FeedPollDelay/feedPollDelay` setting in the configuration of your trigger (the value is expected to be in milliseconds).

- Enable monitoring for your Azure Functions
- Azure Cosmos DB .NET SDK Troubleshooting

Use the change feed estimator

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes how you can monitor the progress of your change feed processor instances as they read the change feed.

Why is monitoring progress important?

The change feed processor acts as a pointer that moves forward across your change feed and delivers the changes to a delegate implementation.

Your change feed processor deployment can process changes at a particular rate based on its available resources like CPU, memory, network, and so on.

If this rate is slower than the rate at which your changes happen in your Azure Cosmos container, your processor will start to lag behind.

Identifying this scenario helps understand if we need to scale our change feed processor deployment.

Implement the change feed estimator

Like the change feed processor, the change feed estimator works as a push model. The estimator will measure the difference between the last processed item (defined by the state of the leases container) and the latest change in the container, and push this value to a delegate. The interval at which the measurement is taken can also be customized with a default value of 5 seconds.

As an example, if your change feed processor is defined like this:

```
Container leaseContainer = client.GetContainer(databaseId, Program.leasesContainer);
Container monitoredContainer = client.GetContainer(databaseId, Program.monitoredContainer);
ChangeFeedProcessor changeFeedProcessor = monitoredContainer
    .GetChangeFeedProcessorBuilder<ToDoItem>("changeFeedEstimator", Program.HandleChangesAsync)
        .WithInstanceName("consoleHost")
        .WithLeaseContainer(leaseContainer)
        .Build();
```

The correct way to initialize an estimator to measure that processor would be using `GetChangeFeedEstimatorBuilder` like so:

```
ChangeFeedProcessor changeFeedEstimator = monitoredContainer
    .GetChangeFeedEstimatorBuilder("changeFeedEstimator", Program.HandleEstimationAsync,
TimeSpan.FromMilliseconds(1000))
    .WithLeaseContainer(leaseContainer)
    .Build();
```

Where both the processor and the estimator share the same `leaseContainer` and the same name.

The other two parameters are the delegate, which will receive a number that represents **how many changes are pending to be read** by the processor, and the time interval at which you want this measurement to be taken.

An example of a delegate that receives the estimation is:

```
static async Task HandleEstimationAsync(long estimation, CancellationToken cancellationToken)
{
    if (estimation > 0)
    {
        Console.WriteLine($"\tEstimator detected {estimation} items pending to be read by the Processor.");
    }

    await Task.Delay(0);
}
```

You can send this estimation to your monitoring solution and use it to understand how your progress is behaving over time.

> **NOTE**
>
> The change feed estimator does not need to be deployed as part of your change feed processor, nor be part of the same project. It can be independent and run in a completely different instance. It just needs to use the same name and lease configuration.

Next steps

You can now proceed to learn more about change feed processor in the following articles:

- Overview of change feed processor
- Change feed processor start time

Migrate from the change feed processor library to the Azure Cosmos DB .NET V3 SDK

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes the required steps to migrate an existing application's code that uses the change feed processor library to the change feed feature in the latest version of the .NET SDK (also referred as .NET V3 SDK).

Required code changes

The .NET V3 SDK has several breaking changes, the following are the key steps to migrate your application:

1. Convert the `DocumentCollectionInfo` instances into `Container` references for the monitored and leases containers.
2. Customizations that use `WithProcessorOptions` should be updated to use `WithLeaseConfiguration` and `WithPollInterval` for intervals, `WithStartTime` for start time, and `WithMaxItems` to define the maximum item count.
3. Set the `processorName` on `GetChangeFeedProcessorBuilder` to match the value configured on `ChangeFeedProcessorOptions.LeasePrefix`, or use `string.Empty` otherwise.
4. The changes are no longer delivered as a `IReadOnlyList<Document>`, instead, it's a `IReadOnlyCollection<T>` where `T` is a type you need to define, there is no base item class anymore.
5. To handle the changes, you no longer need an implementation, instead you need to define a delegate. The delegate can be a static Function or, if you need to maintain state across executions, you can create your own class and pass an instance method as delegate.

For example, if the original code to build the change feed processor looks as follows:

```
ChangeFeedProcessorLibrary.DocumentCollectionInfo monitoredCollectionInfo = new
ChangeFeedProcessorLibrary.DocumentCollectionInfo()
{
    DatabaseName = databaseId,
    CollectionName = Program.monitoredContainer,
    Uri = new Uri(configuration["EndPointUrl"]),
    MasterKey = configuration["AuthorizationKey"]
};

ChangeFeedProcessorLibrary.DocumentCollectionInfo leaseCollectionInfo = new
ChangeFeedProcessorLibrary.DocumentCollectionInfo()
{
    DatabaseName = databaseId,
    CollectionName = Program.leasesContainer,
    Uri = new Uri(configuration["EndPointUrl"]),
    MasterKey = configuration["AuthorizationKey"]
};

ChangeFeedProcessorLibrary.ChangeFeedProcessorBuilder builder = new
ChangeFeedProcessorLibrary.ChangeFeedProcessorBuilder();
var oldChangeFeedProcessor = await builder
    .WithHostName("consoleHost")
    .WithProcessorOptions(new ChangeFeedProcessorLibrary.ChangeFeedProcessorOptions
    {
        StartFromBeginning = true,
        LeasePrefix = "MyLeasePrefix",
        MaxItemCount = 10,
        FeedPollDelay = TimeSpan.FromSeconds(1)
    })
    .WithFeedCollection(monitoredCollectionInfo)
    .WithLeaseCollection(leaseCollectionInfo)
    .WithObserver<ChangeFeedObserver>()
    .BuildAsync();
```

The migrated code will look like:

```
Container leaseContainer = client.GetContainer(databaseId, Program.leasesContainer);
Container monitoredContainer = client.GetContainer(databaseId, Program.monitoredContainer);
ChangeFeedProcessor changeFeedProcessor = monitoredContainer
    .GetChangeFeedProcessorBuilder<ToDoItem>("MyLeasePrefix", Program.HandleChangesAsync)
        .WithInstanceName("consoleHost")
        .WithLeaseContainer(leaseContainer)
        .WithMaxItems(10)
        .WithPollInterval(TimeSpan.FromSeconds(1))
        .WithStartTime(DateTime.MinValue.ToUniversalTime())
        .Build();
```

And the delegate, can be a static method:

```
static async Task HandleChangesAsync(IReadOnlyCollection<ToDoItem> changes, CancellationToken
cancellationToken)
{
    foreach (ToDoItem item in changes)
    {
        Console.WriteLine($"\tDetected operation for item with id {item.id}, created at
{item.creationTime}.");
        // Simulate work
        await Task.Delay(1);
    }
}
```

State and lease container

Similar to the change feed processor library, the change feed feature in .NET V3 SDK uses a lease container to store the state. However, the schemas are different.

The SDK V3 change feed processor will detect any old library state and migrate it to the new schema automatically upon the first execution of the migrated application code.

You can safely stop the application using the old code, migrate the code to the new version, start the migrated application, and any changes that happened while the application was stopped, will be picked up and processed by the new version.

How to create a Java application that uses Azure Cosmos DB SQL API and change feed processor

11/2/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

This how-to guide walks you through a simple Java application which uses the Azure Cosmos DB SQL API to insert documents into an Azure Cosmos DB container, while maintaining a materialized view of the container using Change Feed and Change Feed Processor. The Java application communicates with the Azure Cosmos DB SQL API using Azure Cosmos DB Java SDK v4.

> **IMPORTANT**
>
> This tutorial is for Azure Cosmos DB Java SDK v4 only. Please view the Azure Cosmos DB Java SDK v4 Release notes, Maven repository, Azure Cosmos DB Java SDK v4 performance tips, and Azure Cosmos DB Java SDK v4 troubleshooting guide for more information. If you are currently using an older version than v4, see the Migrate to Azure Cosmos DB Java SDK v4 guide for help upgrading to v4.

Prerequisites

- The URI and key for your Azure Cosmos DB account
- Maven
- Java 8

Background

The Azure Cosmos DB change feed provides an event-driven interface to trigger actions in response to document insertion. This has many uses. For example in applications which are both read and write heavy, a chief use of change feed is to create a real-time **materialized view** of a container as it is ingesting documents. The materialized view container will hold the same data but partitioned for efficient reads, making the application both read and write efficient.

The work of managing change feed events is largely taken care of by the change feed Processor library built into the SDK. This library is powerful enough to distribute change feed events among multiple workers, if that is desired. All you have to do is provide the change feed library a callback.

This simple example demonstrates change feed Processor library with a single worker creating and deleting documents from a materialized view.

Setup

If you have not already done so, clone the app example repo:

```
git clone https://github.com/Azure-Samples/azure-cosmos-java-sql-app-example.git
```

Open a terminal in the repo directory. Build the app by running

```
mvn clean package
```

Walkthrough

1. As a first check, you should have an Azure Cosmos DB account. Open the **Azure portal** in your browser, go to your Azure Cosmos DB account, and in the left pane navigate to **Data Explorer**.

2. Run the app in the terminal using the following command:

```
mvn exec:java -Dexec.mainClass="com.azure.cosmos.workedappexample.SampleGroceryStore" -
DACCOUNT_HOST="your-account-uri" -DACCOUNT_KEY="your-account-key" -Dexec.cleanupDaemonThreads=false
```

3. Press enter when you see

```
Press enter to create the grocery store inventory system...
```

then return to the Azure portal Data Explorer in your browser. You will see a database **GroceryStoreDatabase** has been added with three empty containers:

- **InventoryContainer** - The inventory record for our example grocery store, partitioned on item `id` which is a UUID.
- **InventoryContainer-pktype** - A materialized view of the inventory record, optimized for queries over item `type`
- **InventoryContainer-leases** - A leases container is always needed for change feed; leases track the app's progress in reading the change feed.

4. In the terminal, you should now see a prompt

```
Press enter to start creating the materialized view...
```

Press enter. Now the following block of code will execute and initialize the change feed processor on another thread:

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
changeFeedProcessorInstance = getChangeFeedProcessor("SampleHost_1", feedContainer, leaseContainer);
changeFeedProcessorInstance.start()
    .subscribeOn(Schedulers.elastic())
    .doOnSuccess(aVoid -> {
        isProcessorRunning.set(true);
    })
    .subscribe();

while (!isProcessorRunning.get()); //Wait for Change Feed processor start
```

`"SampleHost_1"` is the name of the Change Feed processor worker. `changeFeedProcessorInstance.start()` is what actually starts the Change Feed processor.

Return to the Azure portal Data Explorer in your browser. Under the **InventoryContainer-leases** container, click **items** to see its contents. You will see that Change Feed Processor has populated the lease container, i.e. the processor has assigned the `SampleHost_1` worker a lease on some partitions of the **InventoryContainer**.

5. Press enter again in the terminal. This will trigger 10 documents to be inserted into **InventoryContainer**. Each document insertion appears in the change feed as JSON; the following callback code handles these events by mirroring the JSON documents into a materialized view:

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
public static ChangeFeedProcessor getChangeFeedProcessor(String hostName, CosmosAsyncContainer
feedContainer, CosmosAsyncContainer leaseContainer) {
    ChangeFeedProcessorOptions cfOptions = new ChangeFeedProcessorOptions();
    cfOptions.setFeedPollDelay(Duration.ofMillis(100));
    cfOptions.setStartFromBeginning(true);
    return new ChangeFeedProcessorBuilder()
        .options(cfOptions)
        .hostName(hostName)
        .feedContainer(feedContainer)
        .leaseContainer(leaseContainer)
        .handleChanges((List<JsonNode> docs) -> {
            for (JsonNode document : docs) {
                    //Duplicate each document update from the feed container into the materialized view
container
                    updateInventoryTypeMaterializedView(document);
            }

        })
        .buildChangeFeedProcessor();
}

private static void updateInventoryTypeMaterializedView(JsonNode document) {
    typeContainer.upsertItem(document).subscribe();
}
```

6. Allow the code to run 5-10sec. Then return to the Azure portal Data Explorer and navigate to **InventoryContainer > items**. You should see that items are being inserted into the inventory container; note the partition key (`id`).

7. Now, in Data Explorer navigate to **InventoryContainer-pktype > items**. This is the materialized view - the items in this container mirror **InventoryContainer** because they were inserted programmatically by change feed. Note the partition key (`type`). So this materialized view is optimized for queries filtering over `type` , which would be inefficient on **InventoryContainer** because it is partitioned on `id` .

8. We're going to delete a document from both **InventoryContainer** and **InventoryContainer-pktype** using just a single `upsertItem()` call. First, take a look at Azure portal Data Explorer. We'll delete the document for which `/type == "plums"` ; it is encircled in red below

Hit enter again to call the function `deleteDocument()` in the example code. This function, shown below, upserts a new version of the document with `/ttl == 5`, which sets document Time-To-Live (TTL) to 5sec.

Java SDK V4 (Maven com.azure::azure-cosmos) Async API

```
public static void deleteDocument() {

    String jsonString =    "{\"id\" : \"" + idToDelete + "\""
            + ","
            + "\"brand\" : \"Jerry's\""
            + ","
            + "\"type\" : \"plums\""
            + ","
            + "\"quantity\" : \"50\""
            + ","
            + "\"ttl\" : 5"
            + "}";

    ObjectMapper mapper = new ObjectMapper();
    JsonNode document = null;

    try {
        document = mapper.readTree(jsonString);
    } catch (Exception e) {
        e.printStackTrace();
    }

    feedContainer.upsertItem(document,new CosmosItemRequestOptions()).block();
}
```

The change feed `feedPollDelay` is set to 100ms; therefore, change feed responds to this update almost instantly and calls `updateInventoryTypeMaterializedView()` shown above. That last function call will upsert the new document with TTL of 5sec into **InventoryContainer-pktype**.

The effect is that after about 5 seconds, the document will expire and be deleted from both containers.

This procedure is necessary because change feed only issues events on item insertion or update, not on item deletion.

9. Press enter one more time to close the program and clean up its resources.

How to write stored procedures, triggers, and user-defined functions in Azure Cosmos DB

12/4/2020 • 11 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB provides language-integrated, transactional execution of JavaScript that lets you write **stored procedures**, **triggers**, and **user-defined functions (UDFs)**. When using the SQL API in Azure Cosmos DB, you can define the stored procedures, triggers, and UDFs in JavaScript language. You can write your logic in JavaScript and execute it inside the database engine. You can create and execute triggers, stored procedures, and UDFs by using Azure portal, the JavaScript language integrated query API in Azure Cosmos DB and the Cosmos DB SQL API client SDKs.

To call a stored procedure, trigger, and user-defined function, you need to register it. For more information, see How to work with stored procedures, triggers, user-defined functions in Azure Cosmos DB.

> **NOTE**
>
> For partitioned containers, when executing a stored procedure, a partition key value must be provided in the request options. Stored procedures are always scoped to a partition key. Items that have a different partition key value will not be visible to the stored procedure. This also applied to triggers as well.

> **TIP**
>
> Cosmos supports deploying containers with stored procedures, triggers and user-defined functions. For more information see Create an Azure Cosmos DB container with server-side functionality.

How to write stored procedures

Stored procedures are written using JavaScript, they can create, update, read, query, and delete items inside an Azure Cosmos container. Stored procedures are registered per collection, and can operate on any document or an attachment present in that collection.

Here is a simple stored procedure that returns a "Hello World" response.

```
var helloWorldStoredProc = {
    id: "helloWorld",
    serverScript: function () {
        var context = getContext();
        var response = context.getResponse();

        response.setBody("Hello, World");
    }
}
```

The context object provides access to all operations that can be performed in Azure Cosmos DB, as well as access to the request and response objects. In this case, you use the response object to set the body of the response to be sent back to the client.

Once written, the stored procedure must be registered with a collection. To learn more, see How to use stored

procedures in Azure Cosmos DB article.

Create an item using stored procedure

When you create an item by using stored procedure, the item is inserted into the Azure Cosmos container and an ID for the newly created item is returned. Creating an item is an asynchronous operation and depends on the JavaScript callback functions. The callback function has two parameters - one for the error object in case the operation fails and another for a return value; in this case, the created object. Inside the callback, you can either handle the exception or throw an error. In case a callback is not provided and there is an error, the Azure Cosmos DB runtime will throw an error.

The stored procedure also includes a parameter to set the description, it's a boolean value. When the parameter is set to true and the description is missing, the stored procedure will throw an exception. Otherwise, the rest of the stored procedure continues to run.

The following example stored procedure takes an array of new Azure Cosmos items as input, inserts it into the Azure Cosmos container and returns the count of the items inserted. In this example, we are leveraging the ToDoList sample from the Quickstart .NET SQL API

```
function createToDoItems(items) {
    var collection = getContext().getCollection();
    var collectionLink = collection.getSelfLink();
    var count = 0;

    if (!items) throw new Error("The array is undefined or null.");

    var numItems = items.length;

    if (numItems == 0) {
        getContext().getResponse().setBody(0);
        return;
    }

    tryCreate(items[count], callback);

    function tryCreate(item, callback) {
        var options = { disableAutomaticIdGeneration: false };

        var isAccepted = collection.createDocument(collectionLink, item, options, callback);

        if (!isAccepted) getContext().getResponse().setBody(count);
    }

    function callback(err, item, options) {
        if (err) throw err;
        count++;
        if (count >= numItems) {
            getContext().getResponse().setBody(count);
        } else {
            tryCreate(items[count], callback);
        }
    }
}
```

Arrays as input parameters for stored procedures

When defining a stored procedure in Azure portal, input parameters are always sent as a string to the stored procedure. Even if you pass an array of strings as an input, the array is converted to string and sent to the stored procedure. To work around this, you can define a function within your stored procedure to parse the string as an array. The following code shows how to parse a string input parameter as an array:

```
function sample(arr) {
    if (typeof arr === "string") arr = JSON.parse(arr);

    arr.forEach(function(a) {
        // do something here
        console.log(a);
    });
}
```

Transactions within stored procedures

You can implement transactions on items within a container by using a stored procedure. The following example uses transactions within a fantasy football gaming app to trade players between two teams in a single operation. The stored procedure attempts to read the two Azure Cosmos items each corresponding to the player IDs passed in as an argument. If both players are found, then the stored procedure updates the items by swapping their teams. If any errors are encountered along the way, the stored procedure throws a JavaScript exception that implicitly aborts the transaction.

```
// JavaScript source code
function tradePlayers(playerId1, playerId2) {
    var context = getContext();
    var container = context.getCollection();
    var response = context.getResponse();

    var player1Document, player2Document;

    // query for players
    var filterQuery =
    {
        'query' : 'SELECT * FROM Players p where p.id = @playerId1',
        'parameters' : [{'name':'@playerId1', 'value':playerId1}]
    };

    var accept = container.queryDocuments(container.getSelfLink(), filterQuery, {},
        function (err, items, responseOptions) {
            if (err) throw new Error("Error" + err.message);

            if (items.length != 1) throw "Unable to find both names";
            player1Item = items[0];

            var filterQuery2 =
            {
                'query' : 'SELECT * FROM Players p where p.id = @playerId2',
                'parameters' : [{'name':'@playerId2', 'value':playerId2}]
            };
            var accept2 = container.queryDocuments(container.getSelfLink(), filterQuery2, {},
                function (err2, items2, responseOptions2) {
                    if (err2) throw new Error("Error" + err2.message);
                    if (items2.length != 1) throw "Unable to find both names";
                    player2Item = items2[0];
                    swapTeams(player1Item, player2Item);
                    return;
                });
            if (!accept2) throw "Unable to read player details, abort ";
        });

    if (!accept) throw "Unable to read player details, abort ";

    // swap the two players' teams
    function swapTeams(player1, player2) {
        var player2NewTeam = player1.team;
        player1.team = player2.team;
        player2.team = player2NewTeam;

        var accept = container.replaceDocument(player1._self, player1,
            function (err, itemReplaced) {
                if (err) throw "Unable to update player 1, abort ";

                var accept2 = container.replaceDocument(player2._self, player2,
                    function (err2, itemReplaced2) {
                        if (err) throw "Unable to update player 2, abort"
                    });

                if (!accept2) throw "Unable to update player 2, abort";
            });

        if (!accept) throw "Unable to update player 1, abort";
    }
}
```

Bounded execution within stored procedures

The following is an example of a stored procedure that bulk-imports items into an Azure Cosmos container. The stored procedure handles bounded execution by checking the boolean return value from `createDocument`, and then

uses the count of items inserted in each invocation of the stored procedure to track and resume progress across batches.

```
function bulkImport(items) {
    var container = getContext().getCollection();
    var containerLink = container.getSelfLink();

    // The count of imported items, also used as current item index.
    var count = 0;

    // Validate input.
    if (!items) throw new Error("The array is undefined or null.");

    var itemsLength = items.length;
    if (itemsLength == 0) {
        getContext().getResponse().setBody(0);
    }

    // Call the create API to create an item.
    tryCreate(items[count], callback);

    // Note that there are 2 exit conditions:
    // 1) The createDocument request was not accepted.
    //    In this case the callback will not be called, we just call setBody and we are done.
    // 2) The callback was called items.length times.
    //    In this case all items were created and we don't need to call tryCreate anymore. Just call setBody
and we are done.
    function tryCreate(item, callback) {
        var isAccepted = container.createDocument(containerLink, item, callback);

        // If the request was accepted, callback will be called.
        // Otherwise report current count back to the client,
        // which will call the script again with remaining set of items.
        if (!isAccepted) getContext().getResponse().setBody(count);
    }

    // This is called when container.createDocument is done in order to process the result.
    function callback(err, item, options) {
        if (err) throw err;

        // One more item has been inserted, increment the count.
        count++;

        if (count >= itemsLength) {
            // If we created all items, we are done. Just set the response.
            getContext().getResponse().setBody(count);
        } else {
            // Create next document.
            tryCreate(items[count], callback);
        }
    }
}
```

Async await with stored procedures

The following is an example of a stored procedure that uses async-await with Promises using a helper function. The stored procedure queries for an item and replaces it.

```
function async_sample() {
    const ERROR_CODE = {
        NotAccepted: 429
    };

    const asyncHelper = {
        queryDocuments(sqlQuery, options) {
            return new Promise((resolve, reject) => {
                const isAccepted = __.queryDocuments(__.getSelfLink(), sqlQuery, options, (err, feed, options)
=> {
                    if (err) reject(err);
                    resolve({ feed, options });
                });
                if (!isAccepted) reject(new Error(ERROR_CODE.NotAccepted, "replaceDocument was not
accepted."));
            });
        },

        replaceDocument(doc) {
            return new Promise((resolve, reject) => {
                const isAccepted = __.replaceDocument(doc._self, doc, (err, result, options) => {
                    if (err) reject(err);
                    resolve({ result, options });
                });
                if (!isAccepted) reject(new Error(ERROR_CODE.NotAccepted, "replaceDocument was not
accepted."));
            });
        }
    };

    async function main() {
        let continuation;
        do {
            let { feed, options } = await asyncHelper.queryDocuments("SELECT * from c", { continuation });

            for (let doc of feed) {
                doc.newProp = 1;
                await asyncHelper.replaceDocument(doc);
            }

            continuation = options.continuation;
        } while (continuation);
    }

    main().catch(err => getContext().abort(err));
}
```

How to write triggers

Azure Cosmos DB supports pre-triggers and post-triggers. Pre-triggers are executed before modifying a database item and post-triggers are executed after modifying a database item.

Pre-triggers

The following example shows how a pre-trigger is used to validate the properties of an Azure Cosmos item that is being created. In this example, we are leveraging the ToDoList sample from the Quickstart .NET SQL API, to add a timestamp property to a newly added item if it doesn't contain one.

```
function validateToDoItemTimestamp() {
    var context = getContext();
    var request = context.getRequest();

    // item to be created in the current operation
    var itemToCreate = request.getBody();

    // validate properties
    if (!("timestamp" in itemToCreate)) {
        var ts = new Date();
        itemToCreate["timestamp"] = ts.getTime();
    }

    // update the item that will be created
    request.setBody(itemToCreate);
}
```

Pre-triggers cannot have any input parameters. The request object in the trigger is used to manipulate the request message associated with the operation. In the previous example, the pre-trigger is run when creating an Azure Cosmos item, and the request message body contains the item to be created in JSON format.

When triggers are registered, you can specify the operations that it can run with. This trigger should be created with a `TriggerOperation` value of `TriggerOperation.Create`, which means using the trigger in a replace operation as shown in the following code is not permitted.

For examples of how to register and call a pre-trigger, see pre-triggers and post-triggers articles.

Post-triggers

The following example shows a post-trigger. This trigger queries for the metadata item and updates it with details about the newly created item.

```
function updateMetadata() {
var context = getContext();
var container = context.getCollection();
var response = context.getResponse();

// item that was created
var createdItem = response.getBody();

// query for metadata document
var filterQuery = 'SELECT * FROM root r WHERE r.id = "_metadata"';
var accept = container.queryDocuments(container.getSelfLink(), filterQuery,
    updateMetadataCallback);
if(!accept) throw "Unable to update metadata, abort";

function updateMetadataCallback(err, items, responseOptions) {
    if(err) throw new Error("Error" + err.message);
        if(items.length != 1) throw 'Unable to find metadata document';

        var metadataItem = items[0];

        // update metadata
        metadataItem.createdItems += 1;
        metadataItem.createdNames += " " + createdItem.id;
        var accept = container.replaceDocument(metadataItem._self,
            metadataItem, function(err, itemReplaced) {
                    if(err) throw "Unable to update metadata, abort";
            });
        if(!accept) throw "Unable to update metadata, abort";
        return;
}
```

One thing that is important to note is the transactional execution of triggers in Azure Cosmos DB. The post-trigger runs as part of the same transaction for the underlying item itself. An exception during the post-trigger execution will fail the whole transaction. Anything committed will be rolled back and an exception returned.

For examples of how to register and call a pre-trigger, see pre-triggers and post-triggers articles.

How to write user-defined functions

The following sample creates a UDF to calculate income tax for various income brackets. This user-defined function would then be used inside a query. For the purposes of this example assume there is a container called "Incomes" with properties as follows:

```
{
   "name": "Satya Nadella",
   "country": "USA",
   "income": 70000
}
```

The following is a function definition to calculate income tax for various income brackets:

```
function tax(income) {

        if(income == undefined)
            throw 'no input';

        if (income < 1000)
            return income * 0.1;
        else if (income < 10000)
            return income * 0.2;
        else
            return income * 0.4;
    }
```

For examples of how to register and use a user-defined function, see How to use user-defined functions in Azure Cosmos DB article.

Logging

When using stored procedure, triggers or user-defined functions, you can log the steps using the `console.log()` command. This command will concentrate a string for debugging when `EnableScriptLogging` is set to true as shown in the following example:

```
var response = await client.ExecuteStoredProcedureAsync(
document.SelfLink,
new RequestOptions { EnableScriptLogging = true } );
Console.WriteLine(response.ScriptLog);
```

How to write stored procedures and triggers in Azure Cosmos DB by using the JavaScript query API

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB allows you to perform optimized queries by using a fluent JavaScript interface without any knowledge of SQL language that can be used to write stored procedures or triggers. To learn more about JavaScript Query API support in Azure Cosmos DB, see Working with JavaScript language integrated query API in Azure Cosmos DB article.

Stored procedure using the JavaScript query API

The following code sample is an example of how the JavaScript query API is used in the context of a stored procedure. The stored procedure inserts an Azure Cosmos item that is specified by an input parameter, and updates a metadata document by using the `__.filter()` method, with minSize, maxSize, and totalSize based upon the input item's size property.

> **NOTE**
>
> `__` (double-underscore) is an alias to `getContext().getCollection()` when using the JavaScript query API.

```
/**
 * Insert an item and update metadata doc: minSize, maxSize, totalSize based on item.size.
 */
function insertDocumentAndUpdateMetadata(item) {
  // HTTP error codes sent to our callback function by CosmosDB server.
  var ErrorCode = {
    RETRY_WITH: 449,
  }

  var isAccepted = __.createDocument(__.getSelfLink(), item, {}, function(err, item, options) {
    if (err) throw err;

    // Check the item (ignore items with invalid/zero size and metadata itself) and call updateMetadata.
    if (!item.isMetadata && item.size > 0) {
      // Get the metadata. We keep it in the same container. it's the only item that has .isMetadata = true.
      var result = __.filter(function(x) {
        return x.isMetadata === true
      }, function(err, feed, options) {
        if (err) throw err;

        // We assume that metadata item was pre-created and must exist when this script is called.
        if (!feed || !feed.length) throw new Error("Failed to find the metadata item.");

        // The metadata item.
        var metaItem = feed[0];

        // Update metaDoc.minSize:
        // for 1st document use doc.Size, for all the rest see if it's less than last min.
        if (metaItem.minSize == 0) metaItem.minSize = item.size;
        else metaItem.minSize = Math.min(metaItem.minSize, item.size);

        // Update metaItem.maxSize.
        metaItem.maxSize = Math.max(metaItem.maxSize, item.size);

        // Update metaItem.totalSize.
        metaItem.totalSize += item.size;

        // Update/replace the metadata item in the store.
        var isAccepted = __.replaceDocument(metaItem._self, metaItem, function(err) {
          if (err) throw err;
          // Note: in case concurrent updates causes conflict with ErrorCode.RETRY_WITH, we can't read the
meta again
          //       and update again because due to Snapshot isolation we will read same exact version (we are
in same transaction).
          //       We have to take care of that on the client side.
        });
        if (!isAccepted) throw new Error("replaceDocument(metaItem) returned false.");
      });
      if (!result.isAccepted) throw new Error("filter for metaItem returned false.");
    }
  });
  if (!isAccepted) throw new Error("createDocument(actual item) returned false.");
}
```

How to register and use stored procedures, triggers, and user-defined functions in Azure Cosmos DB

12/4/2020 • 12 minutes to read • Edit Online

APPLIES TO: SQL API

The SQL API in Azure Cosmos DB supports registering and invoking stored procedures, triggers, and user-defined functions (UDFs) written in JavaScript. You can use the SQL API .NET, .NET Core, Java, JavaScript, Node.js, or Python SDKs to register and invoke the stored procedures. Once you have defined one or more stored procedures, triggers, and user-defined functions, you can load and view them in the Azure portal by using Data Explorer.

How to run stored procedures

Stored procedures are written using JavaScript. They can create, update, read, query, and delete items within an Azure Cosmos container. For more information on how to write stored procedures in Azure Cosmos DB, see How to write stored procedures in Azure Cosmos DB article.

The following examples show how to register and call a stored procedure by using the Azure Cosmos DB SDKs. Refer to Create a Document as the source for this stored procedure is saved as `spCreateToDoItem.js`.

> **NOTE**
> For partitioned containers, when executing a stored procedure, a partition key value must be provided in the request options. Stored procedures are always scoped to a partition key. Items that have a different partition key value will not be visible to the stored procedure. This also applied to triggers as well.

Stored procedures - .NET SDK V2

The following example shows how to register a stored procedure by using the .NET SDK V2:

```
string storedProcedureId = "spCreateToDoItems";
StoredProcedure newStoredProcedure = new StoredProcedure
   {
       Id = storedProcedureId,
       Body = File.ReadAllText($@"..\js\{storedProcedureId}.js")
   };
Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
var response = await client.CreateStoredProcedureAsync(containerUri, newStoredProcedure);
StoredProcedure createdStoredProcedure = response.Resource;
```

The following code shows how to call a stored procedure by using the .NET SDK V2:

```
dynamic[] newItems = new dynamic[]
{
    new {
        category = "Personal",
        name = "Groceries",
        description = "Pick up strawberries",
        isComplete = false
    },
    new {
        category = "Personal",
        name = "Doctor",
        description = "Make appointment for check up",
        isComplete = false
    }
};

Uri uri = UriFactory.CreateStoredProcedureUri("myDatabase", "myContainer", "spCreateToDoItem");
RequestOptions options = new RequestOptions { PartitionKey = new PartitionKey("Personal") };
var result = await client.ExecuteStoredProcedureAsync<string>(uri, options, new[] { newItems });
```

Stored procedures - .NET SDK V3

The following example shows how to register a stored procedure by using the .NET SDK V3:

```
string storedProcedureId = "spCreateToDoItems";
StoredProcedureResponse storedProcedureResponse = await client.GetContainer("myDatabase",
"myContainer").Scripts.CreateStoredProcedureAsync(new StoredProcedureProperties
{
    Id = storedProcedureId,
    Body = File.ReadAllText($@"..\js\{storedProcedureId}.js")
});
```

The following code shows how to call a stored procedure by using the .NET SDK V3:

```
dynamic[] newItems = new dynamic[]
{
    new {
        category = "Personal",
        name = "Groceries",
        description = "Pick up strawberries",
        isComplete = false
    },
    new {
        category = "Personal",
        name = "Doctor",
        description = "Make appointment for check up",
        isComplete = false
    }
};

var result = await client.GetContainer("database", "container").Scripts.ExecuteStoredProcedureAsync<string>
("spCreateToDoItem", new PartitionKey("Personal"), new[] { newItems });
```

Stored procedures - Java SDK

The following example shows how to register a stored procedure by using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
StoredProcedure newStoredProcedure = new StoredProcedure(
    "{" +
        "  'id':'spCreateToDoItems'," +
        "  'body':" + new String(Files.readAllBytes(Paths.get("..\\js\\spCreateToDoItems.js"))) +
    "}");
//toBlocking() blocks the thread until the operation is complete and is used only for demo.
StoredProcedure createdStoredProcedure = asyncClient.createStoredProcedure(containerLink, newStoredProcedure,
null)
    .toBlocking().single().getResource();
```

The following code shows how to call a stored procedure by using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
String sprocLink = String.format("%s/sprocs/%s", containerLink, "spCreateToDoItems");
final CountDownLatch successfulCompletionLatch = new CountDownLatch(1);

List<ToDoItem> ToDoItems = new ArrayList<ToDoItem>();

class ToDoItem {
    public String category;
    public String name;
    public String description;
    public boolean isComplete;
}

ToDoItem newItem = new ToDoItem();
newItem.category = "Personal";
newItem.name = "Groceries";
newItem.description = "Pick up strawberries";
newItem.isComplete = false;

ToDoItems.add(newItem)

newItem.category = "Personal";
newItem.name = "Doctor";
newItem.description = "Make appointment for check up";
newItem.isComplete = false;

ToDoItems.add(newItem)

RequestOptions requestOptions = new RequestOptions();
requestOptions.setPartitionKey(new PartitionKey("Personal"));

Object[] storedProcedureArgs = new Object[] { ToDoItems };
asyncClient.executeStoredProcedure(sprocLink, requestOptions, storedProcedureArgs)
    .subscribe(storedProcedureResponse -> {
        String storedProcResultAsString = storedProcedureResponse.getResponseAsString();
        successfulCompletionLatch.countDown();
        System.out.println(storedProcedureResponse.getActivityId());
    }, error -> {
        successfulCompletionLatch.countDown();
        System.err.println("an error occurred while executing the stored procedure: actual cause: "
                + error.getMessage());
    });

successfulCompletionLatch.await();
```

Stored procedures - JavaScript SDK

The following example shows how to register a stored procedure by using the JavaScript SDK

```
const container = client.database("myDatabase").container("myContainer");
const sprocId = "spCreateToDoItems";
await container.scripts.storedProcedures.create({
    id: sprocId,
    body: require(`../js/${sprocId}`)
});
```

The following code shows how to call a stored procedure by using the JavaScript SDK:

```
const newItem = [{
    category: "Personal",
    name: "Groceries",
    description: "Pick up strawberries",
    isComplete: false
}];
const container = client.database("myDatabase").container("myContainer");
const sprocId = "spCreateToDoItems";
const {body: result} = await container.scripts.storedProcedure(sprocId).execute(newItem, {partitionKey:
newItem[0].category});
```

Stored procedures - Python SDK

The following example shows how to register a stored procedure by using the Python SDK:

```
import azure.cosmos.cosmos_client as cosmos_client

url = "your_cosmos_db_account_URI"
key = "your_cosmos_db_account_key"
database_name = 'your_cosmos_db_database_name'
container_name = 'your_cosmos_db_container_name'

with open('../js/spCreateToDoItems.js') as file:
    file_contents = file.read()

sproc = {
    'id': 'spCreateToDoItem',
    'serverScript': file_contents,
}
client = cosmos_client.CosmosClient(url, key)
database = client.get_database_client(database_name)
container = database.get_container_client(container_name)
created_sproc = container.scripts.create_stored_procedure(body=sproc)
```

The following code shows how to call a stored procedure by using the Python SDK:

```
import uuid

new_id= str(uuid.uuid4())

# Creating a document for a container with "id" as a partition key.

new_item =   {
      "id": new_id,
      "category":"Personal",
      "name":"Groceries",
      "description":"Pick up strawberries",
      "isComplete":False
   }
result = container.scripts.execute_stored_procedure(sproc=created_sproc,params=[[new_item]],
partition_key=new_id)
```

How to run pre-triggers

The following examples show how to register and call a pre-trigger by using the Azure Cosmos DB SDKs. Refer to the Pre-trigger example as the source for this pre-trigger is saved as `trgPreValidateToDoItemTimestamp.js`.

When executing, pre-triggers are passed in the RequestOptions object by specifying `PreTriggerInclude` and then passing the name of the trigger in a List object.

> **NOTE**
> Even though the name of the trigger is passed as a List, you can still execute only one trigger per operation.

Pre-triggers - .NET SDK V2

The following code shows how to register a pre-trigger using the .NET SDK V2:

```
string triggerId = "trgPreValidateToDoItemTimestamp";
Trigger trigger = new Trigger
{
    Id =  triggerId,
    Body = File.ReadAllText($@"..\js\{triggerId}.js"),
    TriggerOperation = TriggerOperation.Create,
    TriggerType = TriggerType.Pre
};
Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
await client.CreateTriggerAsync(containerUri, trigger);
```

The following code shows how to call a pre-trigger using the .NET SDK V2:

```
dynamic newItem = new
{
    category = "Personal",
    name = "Groceries",
    description = "Pick up strawberries",
    isComplete = false
};

Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
RequestOptions requestOptions = new RequestOptions { PreTriggerInclude = new List<string> {
"trgPreValidateToDoItemTimestamp" } };
await client.CreateDocumentAsync(containerUri, newItem, requestOptions);
```

Pre-triggers - .NET SDK V3

The following code shows how to register a pre-trigger using the .NET SDK V3:

```
await client.GetContainer("database", "container").Scripts.CreateTriggerAsync(new TriggerProperties
{
    Id = "trgPreValidateToDoItemTimestamp",
    Body = File.ReadAllText("@..\js\trgPreValidateToDoItemTimestamp.js"),
    TriggerOperation = TriggerOperation.Create,
    TriggerType = TriggerType.Pre
});
```

The following code shows how to call a pre-trigger using the .NET SDK V3:

```
dynamic newItem = new
{
    category = "Personal",
    name = "Groceries",
    description = "Pick up strawberries",
    isComplete = false
};

await client.GetContainer("database", "container").CreateItemAsync(newItem, null, new ItemRequestOptions {
PreTriggers = new List<string> { "trgPreValidateToDoItemTimestamp" } });
```

Pre-triggers - Java SDK

The following code shows how to register a pre-trigger using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
String triggerId = "trgPreValidateToDoItemTimestamp";
Trigger trigger = new Trigger();
trigger.setId(triggerId);
trigger.setBody(new String(Files.readAllBytes(Paths.get(String.format("..\\js\\%s.js", triggerId)));
trigger.setTriggerOperation(TriggerOperation.Create);
trigger.setTriggerType(TriggerType.Pre);
//toBlocking() blocks the thread until the operation is complete and is used only for demo.
Trigger createdTrigger = asyncClient.createTrigger(containerLink, trigger, new
RequestOptions()).toBlocking().single().getResource();
```

The following code shows how to call a pre-trigger using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
    Document item = new Document("{ "
            + "\"category\": \"Personal\", "
            + "\"name\": \"Groceries\", "
            + "\"description\": \"Pick up strawberries\", "
            + "\"isComplete\": false, "
            + "}"
            );
RequestOptions requestOptions = new RequestOptions();
requestOptions.setPreTriggerInclude(Arrays.asList("trgPreValidateToDoItemTimestamp"));
//toBlocking() blocks the thread until the operation is complete and is used only for demo.
asyncClient.createDocument(containerLink, item, requestOptions, false).toBlocking();
```

Pre-triggers - JavaScript SDK

The following code shows how to register a pre-trigger using the JavaScript SDK:

```
const container = client.database("myDatabase").container("myContainer");
const triggerId = "trgPreValidateToDoItemTimestamp";
await container.triggers.create({
    id: triggerId,
    body: require(`../js/${triggerId}`),
    triggerOperation: "create",
    triggerType: "pre"
});
```

The following code shows how to call a pre-trigger using the JavaScript SDK:

```
const container = client.database("myDatabase").container("myContainer");
const triggerId = "trgPreValidateToDoItemTimestamp";
await container.items.create({
    category: "Personal",
    name = "Groceries",
    description = "Pick up strawberries",
    isComplete = false
}, {preTriggerInclude: [triggerId]});
```

Pre-triggers - Python SDK

The following code shows how to register a pre-trigger using the Python SDK:

```
import azure.cosmos.cosmos_client as cosmos_client

url = "your_cosmos_db_account_URI"
key = "your_cosmos_db_account_key"
database_name = 'your_cosmos_db_database_name'
container_name = 'your_cosmos_db_container_name'

with open('../js/trgPreValidateToDoItemTimestamp.js') as file:
    file_contents = file.read()

trigger_definition = {
    'id': 'trgPreValidateToDoItemTimestamp',
    'serverScript': file_contents,
    'triggerType': documents.TriggerType.Pre,
    'triggerOperation': documents.TriggerOperation.All
}
client = cosmos_client.CosmosClient(url, key)
database = client.get_database_client(database_name)
container = database.get_container_client(container_name)
trigger = container.scripts.create_trigger(trigger_definition)
```

The following code shows how to call a pre-trigger using the Python SDK:

```
item = {'category': 'Personal', 'name': 'Groceries',
        'description': 'Pick up strawberries', 'isComplete': False}
container.create_item(item, {'pre_trigger_include': 'trgPreValidateToDoItemTimestamp'})
```

How to run post-triggers

The following examples show how to register a post-trigger by using the Azure Cosmos DB SDKs. Refer to the Post-trigger example as the source for this post-trigger is saved as `trgPostUpdateMetadata.js`.

Post-triggers - .NET SDK V2

The following code shows how to register a post-trigger using the .NET SDK V2:

```
string triggerId = "trgPostUpdateMetadata";
Trigger trigger = new Trigger
{
    Id = triggerId,
    Body = File.ReadAllText($@"..\js\{triggerId}.js"),
    TriggerOperation = TriggerOperation.Create,
    TriggerType = TriggerType.Post
};
Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
await client.CreateTriggerAsync(containerUri, trigger);
```

The following code shows how to call a post-trigger using the .NET SDK V2:

```
var newItem = {
    name: "artist_profile_1023",
    artist: "The Band",
    albums: ["Hellujah", "Rotators", "Spinning Top"]
};

RequestOptions options = new RequestOptions { PostTriggerInclude = new List<string> { "trgPostUpdateMetadata"
} };
Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
await client.createDocumentAsync(containerUri, newItem, options);
```

Post-triggers - .NET SDK V3

The following code shows how to register a post-trigger using the .NET SDK V3:

```
await client.GetContainer("database", "container").Scripts.CreateTriggerAsync(new TriggerProperties
{
    Id = "trgPostUpdateMetadata",
    Body = File.ReadAllText(@"..\js\trgPostUpdateMetadata.js"),
    TriggerOperation = TriggerOperation.Create,
    TriggerType = TriggerType.Post
});
```

The following code shows how to call a post-trigger using the .NET SDK V3:

```
var newItem = {
    name: "artist_profile_1023",
    artist: "The Band",
    albums: ["Hellujah", "Rotators", "Spinning Top"]
};

await client.GetContainer("database", "container").CreateItemAsync(newItem, null, new ItemRequestOptions {
PostTriggers = new List<string> { "trgPostUpdateMetadata" } });
```

Post-triggers - Java SDK

The following code shows how to register a post-trigger using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
String triggerId = "trgPostUpdateMetadata";
Trigger trigger = new Trigger();
trigger.setId(triggerId);
trigger.setBody(new String(Files.readAllBytes(Paths.get(String.format("..\\js\\%s.js", triggerId)))));
trigger.setTriggerOperation(TriggerOperation.Create);
trigger.setTriggerType(TriggerType.Post);
Trigger createdTrigger = asyncClient.createTrigger(containerLink, trigger, new
RequestOptions()).toBlocking().single().getResource();
```

The following code shows how to call a post-trigger using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
Document item = new Document(String.format("{ "
    + "\"name\": \"artist_profile_1023\", "
    + "\"artist\": \"The Band\", "
    + "\"albums\": [\"Hellujah\", \"Rotators\", \"Spinning Top\"]"
    + "}"
));
RequestOptions requestOptions = new RequestOptions();
requestOptions.setPostTriggerInclude(Arrays.asList("trgPostUpdateMetadata"));
//toBlocking() blocks the thread until the operation is complete, and is used only for demo.
asyncClient.createDocument(containerLink, item, requestOptions, false).toBlocking();
```

Post-triggers - JavaScript SDK

The following code shows how to register a post-trigger using the JavaScript SDK:

```
const container = client.database("myDatabase").container("myContainer");
const triggerId = "trgPostUpdateMetadata";
await container.triggers.create({
    id: triggerId,
    body: require(`../js/${triggerId}`),
    triggerOperation: "create",
    triggerType: "post"
});
```

The following code shows how to call a post-trigger using the JavaScript SDK:

```
const item = {
    name: "artist_profile_1023",
    artist: "The Band",
    albums: ["Hellujah", "Rotators", "Spinning Top"]
};
const container = client.database("myDatabase").container("myContainer");
const triggerId = "trgPostUpdateMetadata";
await container.items.create(item, {postTriggerInclude: [triggerId]});
```

Post-triggers - Python SDK

The following code shows how to register a post-trigger using the Python SDK:

```
import azure.cosmos.cosmos_client as cosmos_client

url = "your_cosmos_db_account_URI"
key = "your_cosmos_db_account_key"
database_name = 'your_cosmos_db_database_name'
container_name = 'your_cosmos_db_container_name'

with open('../js/trgPostValidateToDoItemTimestamp.js') as file:
    file_contents = file.read()

trigger_definition = {
    'id': 'trgPostValidateToDoItemTimestamp',
    'serverScript': file_contents,
    'triggerType': documents.TriggerType.Post,
    'triggerOperation': documents.TriggerOperation.All
}
client = cosmos_client.CosmosClient(url, key)
database = client.get_database_client(database_name)
container = database.get_container_client(container_name)
trigger = container.scripts.create_trigger(trigger_definition)
```

The following code shows how to call a post-trigger using the Python SDK:

```
item = {'category': 'Personal', 'name': 'Groceries',
        'description': 'Pick up strawberries', 'isComplete': False}
container.create_item(item, {'post_trigger_include': 'trgPreValidateToDoItemTimestamp'})
```

How to work with user-defined functions

The following examples show how to register a user-defined function by using the Azure Cosmos DB SDKs. Refer to this User-defined function example as the source for this post-trigger is saved as `udfTax.js`.

User-defined functions - .NET SDK V2

The following code shows how to register a user-defined function using the .NET SDK V2:

```
string udfId = "Tax";
var udfTax = new UserDefinedFunction
{
    Id = udfId,
    Body = File.ReadAllText($@"..\js\{udfId}.js")
};

Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
await client.CreateUserDefinedFunctionAsync(containerUri, udfTax);
```

The following code shows how to call a user-defined function using the .NET SDK V2:

```
Uri containerUri = UriFactory.CreateDocumentCollectionUri("myDatabase", "myContainer");
var results = client.CreateDocumentQuery<dynamic>(containerUri, "SELECT * FROM Incomes t WHERE
udf.Tax(t.income) > 20000"));

foreach (var result in results)
{
    //iterate over results
}
```

User-defined functions - .NET SDK V3

The following code shows how to register a user-defined function using the .NET SDK V3:

```
await client.GetContainer("database", "container").Scripts.CreateUserDefinedFunctionAsync(new
UserDefinedFunctionProperties
{
    Id = "Tax",
    Body = File.ReadAllText(@"..\js\Tax.js")
});
```

The following code shows how to call a user-defined function using the .NET SDK V3:

```
var iterator = client.GetContainer("database", "container").GetItemQueryIterator<dynamic>("SELECT * FROM
Incomes t WHERE udf.Tax(t.income) > 20000");
while (iterator.HasMoreResults)
{
    var results = await iterator.ReadNextAsync();
    foreach (var result in results)
    {
        //iterate over results
    }
}
```

User-defined functions - Java SDK

The following code shows how to register a user-defined function using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
String udfId = "Tax";
UserDefinedFunction udf = new UserDefinedFunction();
udf.setId(udfId);
udf.setBody(new String(Files.readAllBytes(Paths.get(String.format("..\\js\\%s.js", udfId)))));
//toBlocking() blocks the thread until the operation is complete and is used only for demo.
UserDefinedFunction createdUDF = client.createUserDefinedFunction(containerLink, udf, new
RequestOptions()).toBlocking().single().getResource();
```

The following code shows how to call a user-defined function using the Java SDK:

```
String containerLink = String.format("/dbs/%s/colls/%s", "myDatabase", "myContainer");
Observable<FeedResponse<Document>> queryObservable = client.queryDocuments(containerLink, "SELECT * FROM
Incomes t WHERE udf.Tax(t.income) > 20000", new FeedOptions());
final CountDownLatch completionLatch = new CountDownLatch(1);
queryObservable.subscribe(
        queryResultPage -> {
            System.out.println("Got a page of query result with " +
                    queryResultPage.getResults().size());
        },
        // terminal error signal
        e -> {
            e.printStackTrace();
            completionLatch.countDown();
        },

        // terminal completion signal
        () -> {
            completionLatch.countDown();
        });
completionLatch.await();
```

User-defined functions - JavaScript SDK

The following code shows how to register a user-defined function using the JavaScript SDK:

```
const container = client.database("myDatabase").container("myContainer");
const udfId = "Tax";
await container.userDefinedFunctions.create({
    id: udfId,
    body: require(`../js/${udfId}`)
```

The following code shows how to call a user-defined function using the JavaScript SDK:

```
const container = client.database("myDatabase").container("myContainer");
const sql = "SELECT * FROM Incomes t WHERE udf.Tax(t.income) > 20000";
const {result} = await container.items.query(sql).toArray();
```

User-defined functions - Python SDK

The following code shows how to register a user-defined function using the Python SDK:

```
import azure.cosmos.cosmos_client as cosmos_client

url = "your_cosmos_db_account_URI"
key = "your_cosmos_db_account_key"
database_name = 'your_cosmos_db_database_name'
container_name = 'your_cosmos_db_container_name'

with open('../js/udfTax.js') as file:
    file_contents = file.read()
udf_definition = {
    'id': 'Tax',
    'serverScript': file_contents,
}
client = cosmos_client.CosmosClient(url, key)
database = client.get_database_client(database_name)
container = database.get_container_client(container_name)
udf = container.scripts.create_user_defined_function(udf_definition)
```

The following code shows how to call a user-defined function using the Python SDK:

```
results = list(container.query_items(
    'query': 'SELECT * FROM Incomes t WHERE udf.Tax(t.income) > 20000'))
```

Enable notebooks for Azure Cosmos DB accounts (preview)

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

> **IMPORTANT**
>
> Built-in notebooks for Azure Cosmos DB are currently available in the following Azure regions: Australia East, East US, East US 2, North Europe, South Central US, Southeast Asia, UK South, West Europe and West US 2. To use notebooks, create a new account with notebooks or enable notebooks on an existing account in one of these regions.

Built-in Jupyter notebooks in Azure Cosmos DB enable you to analyze and visualize your data from the Azure portal. This article describes how to enable this feature for your Azure Cosmos DB account.

Enable notebooks in a new Cosmos account

1. Sign into the Azure portal.
2. Select **Create a resource** > **Databases** > **Azure Cosmos DB**.
3. On the **Create Azure Cosmos DB Account** page, select **Notebooks**.

4. Select **Review + create**. You can skip the **Network** and **Tags** option.
5. Review the account settings, and then select **Create**. It takes a few minutes to create the account. Wait for the portal page to display **Your deployment is complete**.

6. Select **Go to resource** to go to the Azure Cosmos DB account page.

7. Navigate to the **Data Explorer** pane. You should now see your notebooks workspace.

Enable notebooks in an existing Cosmos account

You can also enable notebooks on existing accounts. This step needs to be done only once per account.

1. Navigate to the **Data Explorer** pane in your Cosmos account.

2. Select **Enable Notebooks**.

3. This will prompt you to create a new notebooks workspace. Select **Complete setup.**

4. Your account is now enabled to use notebooks!

Create and run your first notebook

To verify that you can use notebooks, select one of notebooks under Sample Notebooks. This will save a copy of the notebook to your workspace and open it.

In this example, we'll use **GettingStarted.ipynb**.

To run the notebook:

1. Select the first code cell that contains Python code.

2. Select **Run** to run the cell. You can also use **Shift + Enter** to run the cell.

3. Refresh the resource pane to see the database and container that has been created.

You can also select **New Notebook** to create a new notebook or upload an existing notebook (.ipynb) file by selecting **Upload File** from the **My Notebooks** menu.

Next steps

Import notebooks from a GitHub repo into Azure Cosmos DB

12/4/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

After you enable notebook support for your Azure Cosmos accounts, you can create new notebooks, upload new notebooks from your local computer, or import the existing notebooks from your GitHub accounts. This article shows how to connect your notebooks workspace to GitHub and import the notebooks from a GitHub repo to your Azure Cosmos account. After importing, you can run them, make changes, and save the changes back to GitHub.

Get notebooks from GitHub

You can connect to your own GitHub repositories or other public GitHub repositories to read, author, and share notebooks in Azure Cosmos DB. Use the following steps to connect to a GitHub account:

1. Sign into Azure portal and navigate to your Azure Cosmos account.
2. Open the **Data Explorer** tab. This tab will show all your existing databases, containers, and notebooks.
3. Select the **Connect to GitHub** menu item.
4. A tab opens where you can choose to connect to **Public repos** only or **Public and private repos**. After choosing the required option, select **Authorize access**. Authorization is required for Azure Cosmos DB to access the repositories in your GitHub account.

5. You are redirected to "github.com" web page where you can confirm the authorization. Select the **Authorize AzureCosmosDBNotebooks** button and enter your GitHub account password in the prompt.
6. After the authorization is successful, it takes you back to your Azure Cosmos account. You can then see all the public/private repos from your GitHub account. You can select a repo from the list available or add a repo directly by using its URL.
7. Once you select the required repo, the repo entry moves from the **Unpinned repos** section to **Pinned repos** section. If needed, you can also choose a specific branch of that repo to import the notebooks from.

8. Select **OK** to complete the import operation. All the notebooks available in the selected branch of your repo are imported into your Azure Cosmos account.

After you integrate with a GitHub account, only you can see the list of repositories and notebooks in your Azure Cosmos account. This statement is true even if multiple users log into the Azure Cosmos DB account and add their own accounts. In other words, multiple users can use the same Azure Cosmos account to connect the notebook workspace to GitHub. However, each user only sees the list of repositories and notebooks they have imported. The notebooks imported by others are not visible to you.

To disconnect your GitHub account from the notebooks workspace, open the **Data Explorer** tab, select ... next to **GitHub repos** and select **Disconnect from GitHub**.

Edit a notebook and push changes to GitHub

You can edit an existing notebook or add a new notebook to the repo and save the changes back to GitHub.

After you edit an existing notebook, select **Save**. A dialog box opens where you can enter the commit message for the changes you have made. Select **Commit** and the notebook in GitHub is updated. You can validate the updates by signing into your GitHub account, and verifying the commit history.

In the regular GitHub flow after committing the changes, you will typically push changes to a remote. However, in this case the commit option serves the purpose of "staging, committing, and pushing" your updates to GitHub.

Next steps

Use built-in notebook commands and features in Azure Cosmos DB Python notebooks (preview)

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

Built-in Jupyter notebooks in Azure Cosmos DB enable you to analyze and visualize your data from the Azure portal. This article describes how to use built-in notebook commands and features to do common operations in Python notebooks.

Install a new package

After you enable notebook support for your Azure Cosmos accounts, you can open a new notebook and install a package.

In a new code cell, insert and run the following code, replacing `PackageToBeInstalled` with the desired Python package.

```
import sys
!{sys.executable} -m pip install PackageToBeInstalled --user
```

This package will be available to use from any notebook in the Azure Cosmos account workspace.

> **TIP**
> If your notebook requires a custom package, we recommend that you add a cell in your notebook to install the package, as packages are removed if you reset the workspace.

Run a SQL query

You can use the `%%sql` magic command to run a SQL query against any container in your account. Use the syntax:

```
%%sql --database {database_id} --container {container_id}
{Query text}
```

- Replace `{database_id}` and `{container_id}` with the name of the database and container in your Cosmos account. If the `--database` and `--container` arguments are not provided, the query will be executed on the default database and container.
- You can run any SQL query that is valid in Azure Cosmos DB. The query text must be on a new line.

For example:

```
%%sql --database RetailDemo --container WebsiteData
SELECT c.Action, c.Price as ItemRevenue, c.Country, c.Item FROM c
```

Run `%%sql?` in a cell to see the help documentation for the sql magic command in the notebook.

Run a SQL query and output to a Pandas DataFrame

You can output the results of a `%%sql` query into a Pandas DataFrame. Use the syntax:

```
%%sql --database {database_id} --container {container_id} --output {outputDataFrameVar}
{Query text}
```

- Replace `{database_id}` and `{container_id}` with the name of the database and container in your Cosmos account. If the `--database` and `--container` arguments are not provided, the query will be executed on the default database and container.
- Replace `{outputDataFrameVar}` with the name of the DataFrame variable that will contain the results.
- You can run any SQL query that is valid in Azure Cosmos DB. The query text must be on a new line.

For example:

```
%%sql --database RetailDemo --container WebsiteData --output df_cosmos
SELECT c.Action, c.Price as ItemRevenue, c.Country, c.Item FROM c
```

```
df_cosmos.head(10)

    Action    ItemRevenue    Country/Region    Item
0    Viewed    9.00    Tunisia    Black Tee
1    Viewed    19.99    Antigua and Barbuda    Flannel Shirt
2    Added    3.75    Guinea-Bissau    Socks
3    Viewed    3.75    Guinea-Bissau    Socks
4    Viewed    55.00    Czech Republic    Rainjacket
5    Viewed    350.00    Iceland    Cosmos T-shirt
6    Added    19.99    Syrian Arab Republic    Button-Up Shirt
7    Viewed    19.99    Syrian Arab Republic    Button-Up Shirt
8    Viewed    33.00    Tuvalu    Red Top
9    Viewed    14.00    Cabo Verde    Flip Flop Shoes
```

Set default database for queries

You can set the default database `%%sql` commands will use for the notebook. Replace `{database_id}` with the name of your database.

```
%database {database_id}
```

Run `%database?` in a cell to see documentation in the notebook.

Set default container for queries

You can set the default container `%%sql` commands will use for the notebook. Replace `{container_id}` with the name of your container.

```
%container {container_id}
```

Run `%container?` in a cell to see documentation in the notebook.

Upload JSON items to a container

You can use the `%%upload` magic command to upload data from a JSON file to a specified Azure Cosmos container. Use the following command to upload the items:

```
%%upload --databaseName {database_id} --containerName {container_id} --url {url_location_of_file}
```

- Replace `{database_id}` and `{container_id}` with the name of the database and container in your Azure Cosmos account. If the `--database` and `--container` arguments are not provided, the query will be executed on the default database and container.
- Replace `{url_location_of_file}` with the location of your JSON file. The file must be an array of valid JSON objects and it should be accessible over the public Internet.

For example:

```
%%upload --database databaseName --container containerName --url
https://contoso.com/path/to/data.json
```

```
Documents successfully uploaded to ContainerName
Total number of documents imported : 2654
Total time taken : 00:00:38.1228087 hours
Total RUs consumed : 25022.58
```

With the output statistics, you can calculate the effective RU/s used to upload the items. For example, if 25,000 RUs were consumed over 38 seconds, the effective RU/s is 25,000 RUs / 38 seconds = 658 RU/s.

Run another notebook in current notebook

You can use the `%%run` magic command to run another notebook in your workspace from your current notebook. Use the syntax:

```
%%run ./path/to/{notebookName}.ipynb
```

Replace `{notebookName}` with the name of the notebook you want to run. The notebook must be in your current 'My Notebooks' workspace.

Use built-in nteract data explorer

You can use the built-in nteract data explorer to filter and visualize a DataFrame. To enable this feature, set the option `pd.options.display.html.table_schema` to `True` and `pd.options.display.max_rows` to the desired value (you can set `pd.options.display.max_rows` to `None` to show all results).

```
import pandas as pd
pd.options.display.html.table_schema = True
pd.options.display.max_rows = None

df_cosmos.groupby("Item").size()
```

Use the built-in Python SDK

Version 4 of the Azure Cosmos DB Python SDK for SQL API is installed and included in the notebook environment for the Azure Cosmos account.

Use the built-in `cosmos_client` instance to run any SDK operation.

For example:

```
## Import modules as needed
from azure.cosmos.partition_key import PartitionKey

## Create a new database if it doesn't exist
database = cosmos_client.create_database_if_not_exists('RetailDemo')

## Create a new container if it doesn't exist
container = database.create_container_if_not_exists(id='WebsiteData',
partition_key=PartitionKey(path='/CartID'))
```

See Python SDK samples.

> **IMPORTANT**
>
> The built-in Python SDK is only supported for SQL (Core) API accounts. For other APIs, you will need to install the relevant Python driver that corresponds to the API.

Create a custom instance of `cosmos_client`

For more flexibility, you can create a custom instance of `cosmos_client` in order to:

- Customize the connection policy
- Run operations against a different Azure Cosmos account than the one you are in

You can access the connection string and primary key of the current account via the environment variables.

```
import azure.cosmos.cosmos_client as cosmos
import azure.cosmos.documents as documents

# These should be set to a region you've added for Azure Cosmos DB
region_1 = "Central US"
region_2 = "East US 2"

custom_connection_policy = documents.ConnectionPolicy()
custom_connection_policy.PreferredLocations = [region_1, region_2] # Set the order of regions the SDK will
route requests to. The regions should be regions you've added for Cosmos, otherwise this will error.

# Create a new instance of CosmosClient, getting the endpoint and key from the environment variables
custom_client = cosmos.CosmosClient(url=COSMOS.ENDPOINT, credential=COSMOS.KEY,
connection_policy=custom_connection_policy)
```

Access the account endpoint and primary key env variables

You can access the built-in endpoint and key of the account your notebook is in.

```
endpoint = COSMOS.ENDPOINT
primary_key = COSMOS.KEY
```

> **IMPORTANT**
>
> The `COSMOS.ENDPOINT` and `COSMOS.KEY` variables are only applicable for SQL API. For other APIs, find the endpoint and key in the **Connection Strings** or **Keys** blade in your Azure Cosmos account.

Reset notebooks workspace

To reset the notebooks workspace to the default settings, select **Reset Workspace** on the command bar. This will remove any custom installed packages and restart the Jupyter server. Your notebooks, files, and Azure Cosmos resources will not be affected.

Use built-in notebook commands and features in Azure Cosmos DB C# notebooks (preview)

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

Built-in Jupyter notebooks in Azure Cosmos DB enable you to analyze and visualize your data from the Azure portal. This article describes how to use built-in notebook commands and features to do common operations in C# notebooks.

Install a new NuGet package

After you enable notebook support for your Azure Cosmos accounts, you can open a new notebook and install a package.

In a new code cell, insert and run the following code, replacing `PackageToBeInstalled` with the desired NuGet package, and `optionalVersion` with a specific version of the package if desired.

```
#r "nuget: PackageToBeInstalled, optionalVersion"
```

You can install multiple NuGet packages in the same cell. Packages will be available to use from any notebook in the Azure Cosmos account workspace.

Currently, the C# notebooks workspace does not support recursive resolution of NuGet packages. If a NuGet package has dependencies on other NuGet packages that are not currently installed, you have to explicitly reference them along with the parent package.

> **TIP**
> If your notebook requires a custom package, we recommend that you add a cell to your notebook to install the package and make it the first cell. This reduces the chance of conflicts with other packages that Azure Cosmos DB loads by default. It is also easy to re-install the packages if you reset the workspace, which removes all packages.

Use the built-in Azure Cosmos DB .NET SDK

Version 3 of the Azure Cosmos DB .NET SDK for SQL API is installed and included in the notebook environment for the Azure Cosmos account.

Create an instance of `CosmosClient` to run any SDK operation.

For example:

```
// Include usings
using System;
using Microsoft.Azure.Cosmos; //namespace for Azure Cosmos DB .NET V3 SDK
using System.Collections;

// Initialize a new instance of CosmosClient using the built-in account endpoint and key parameters
CosmosClient cosmosClient = new CosmosClient(Cosmos.Endpoint, Cosmos.Key);

// Create a new database and container with 400 RU/s
Database database = await cosmosClient.CreateDatabaseIfNotExistsAsync("DatabaseName");
Container container = await database.CreateContainerIfNotExistsAsync("ContainerName", "/partitionKey", 400);
```

To learn more, see the .NET V3 SDK samples.

> **IMPORTANT**
>
> The built-in Azure Cosmos DB .NET SDK is only supported for SQL (Core) API accounts. For other APIs, you will need to install the relevant .NET driver that corresponds to the API.

Set custom options using `CosmosClientOptions`

For more flexibility, you can set the custom `CosmosClientOptions` property and pass it in your `CosmosClient` instance. You can use this property to:

- Set an application name in the user-agent suffix to include it in every request.
- Set the preferred region to be used when running operations against the service.
- Set a custom retry policy to handle rate-limited requests.

See the CosmosClientOptions API reference article for all the supported settings. The following is an example that shows how to set `cosmosClientOptions` property:

```
using Microsoft.Azure.Cosmos;

// Configure CosmosClientOptions
var cosmosClientOptions = new CosmosClientOptions
{
    ApplicationName = "ContosoNotebookAppName",
    ApplicationRegion = Regions.RegionName, // By default, this is the region you first created your account
in
    MaxRetryAttemptsOnRateLimitedRequests = 9, // By default, this value is 9
};

var client = new CosmosClient(Cosmos.Endpoint, Cosmos.Key, cosmosClientOptions);
```

Access the account endpoint and primary key variables

You can access the built-in endpoint and key of the Azure Cosmos account where your notebook exists.

```
var key = Cosmos.Key;
var endpoint = Cosmos.Endpoint;
```

> **IMPORTANT**
>
> The `Cosmos.Key` and `Cosmos.Endpoint` variables are only applicable for SQL API. For other APIs, find the endpoint and key in the **Connection Strings** or **Keys** blade in your Azure Cosmos account.

Print console output in C# code

In your C# code, you can use the Display.AsMarkdown() syntax with string interpolation to print console output that will appear when you run the cell.

For example:

```
// Print text in the output
Display.AsMarkdown($"Hello world!");

// Print a variable in the output
for (int i = 0; i < 5; i++) {
    Display.AsMarkdown($"Printing out variable: {i}");
}
```

> **IMPORTANT**
>
> Console.WriteLine() syntax is not currently supported in C# notebooks. Use Display.AsMarkdown to print console output from your program.

Use built-in nteract data explorer

You can use the built-in nteract data explorer to filter and visualize a collection of items. In a cell, put the variable you want to visualize in the last line, which is automatically displayed in nteract when you run the cell.

For example, in the *GetingStarted_Csharp.ipynb* example, we can print out the variable with our result, the `telemetryEvents`. See the GettingStarted_Csharp.ipynb notebook for the entire sample.

Use built-in dictionary viewer

You can use the built-in dictionary viewer to view a variable. In a cell, put the variable you want to visualize in the last line, which will be automatically displayed when the cell is run.

Upload JSON items to a container

You can use the `%%upload` magic command to upload data from a JSON file to a specified Azure Cosmos container. Use the following command to upload the items:

```
%%upload --databaseName {database_id} --containerName {container_id} --url {url_location_of_file}
```

- Replace `{database_id}` and `{container_id}` with the name of the database and container in your Azure Cosmos account.
- Replace `{url_location_of_file}` with the location of your JSON file. The file must be an array of valid JSON objects and it should be accessible over the public Internet.

For example:

```
%%upload --database databaseName --container containerName --url
https://contoso.com/path/to/data.json
```

```
Documents successfully uploaded to ContainerName
Total number of documents imported : 2654
Total time taken : 00:00:38.1228087 hours
Total RUs consumed : 25022.58
```

With the output statistics, you can calculate the effective RU/s used to upload the items. For example, if 25,000 RUs

were consumed over 38 seconds, the effective RU/s is 25,000 RUs / 38 seconds = 658 RU/s.

Run another notebook in current notebook

You can use the `%%run` magic command to run another notebook in your workspace from your current notebook. Use the syntax:

```
%%run ./path/to/{notebookName}.ipynb
```

Replace `{notebookName}` with the name of the notebook you want to run. The notebook must be in your current 'My Notebooks' workspace.

Reset notebooks workspace

To reset the notebooks workspace to the default settings, select **Reset Workspace** on the command bar. This will remove any custom installed packages and restart the Jupyter server. Your notebooks, files, and Azure Cosmos resources will not be affected.

Next steps

Azure Cosmos DB bulk executor library overview

11/2/2020 • 2 minutes to read • Edit Online

APPLIES TO: SQL API

Azure Cosmos DB is a fast, flexible, and globally distributed database service that is designed to elastically scale out to support:

- Large read and write throughput (millions of operations per second).
- Storing high volumes of (hundreds of terabytes, or even more) transactional and operational data with predictable millisecond latency.

The bulk executor library helps you leverage this massive throughput and storage. The bulk executor library allows you to perform bulk operations in Azure Cosmos DB through bulk import and bulk update APIs. You can read more about the features of bulk executor library in the following sections.

> **NOTE**
> Currently, bulk executor library supports import and update operations and this library is supported by Azure Cosmos DB SQL API and Gremlin API accounts only.

> **IMPORTANT**
> The bulk executor library is not currently supported on serverless accounts. On .NET, it is recommended to use the bulk support available in the V3 version of the SDK.

Key features of the bulk executor library

- It significantly reduces the client-side compute resources needed to saturate the throughput allocated to a container. A single threaded application that writes data using the bulk import API achieves 10 times greater write throughput when compared to a multi-threaded application that writes data in parallel while saturating the client machine's CPU.
- It abstracts away the tedious tasks of writing application logic to handle rate limiting of request, request timeouts, and other transient exceptions by efficiently handling them within the library.
- It provides a simplified mechanism for applications performing bulk operations to scale out. A single bulk executor instance running on an Azure VM can consume greater than 500K RU/s and you can achieve a higher throughput rate by adding additional instances on individual client VMs.
- It can bulk import more than a terabyte of data within an hour by using a scale-out architecture.
- It can bulk update existing data in Azure Cosmos containers as patches.

How does the bulk executor operate?

When a bulk operation to import or update documents is triggered with a batch of entities, they are initially shuffled into buckets corresponding to their Azure Cosmos DB partition key range. Within each bucket that corresponds to a partition key range, they are broken down into mini-batches and each mini-batch act as a payload that is committed on the server-side. The bulk executor library has built in optimizations for concurrent execution of these mini-batches both within and across partition key ranges. Following image illustrates how bulk

executor batches data into different partition keys:

Azure Cosmos DB Bulk Executor Library

The bulk executor library makes sure to maximally utilize the throughput allocated to a collection. It uses anAIMD-style congestion control mechanism for each Azure Cosmos DB partition key rangeto efficiently handle rate limiting and timeouts.

Next Steps

- Learn more by trying out the sample applications consuming the bulk executor library in .NET and Java.
- Check out the bulk executor SDK information and release notes in .NET and Java.
- The bulk executor library is integrated into the Cosmos DB Spark connector, to learn more, see Azure Cosmos DB Spark connector article.
- The bulk executor library is also integrated into a new version of Azure Cosmos DB connector for Azure Data Factory to copy data.

Use the bulk executor .NET library to perform bulk operations in Azure Cosmos DB

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

> **NOTE**
>
> This bulk executor library described in this article is maintained for applications using the .NET SDK 2.x version. For new applications, you can use the **bulk support** that is directly available with the .NET SDK version 3.x and it does not require any external library.

> If you are currently using the bulk executor library and planning to migrate to bulk support on the newer SDK, use the steps in the Migration guide to migrate your application.

This tutorial provides instructions on using the bulk executor .NET library to import and update documents to an Azure Cosmos container. To learn about the bulk executor library and how it helps you leverage massive throughput and storage, see the bulk executor library overview article. In this tutorial, you will see a sample .NET application that bulk imports randomly generated documents into an Azure Cosmos container. After importing, it shows you how you can bulk update the imported data by specifying patches as operations to perform on specific document fields.

Currently, bulk executor library is supported by the Azure Cosmos DB SQL API and Gremlin API accounts only. This article describes how to use the bulk executor .NET library with SQL API accounts. To learn about using the bulk executor .NET library with Gremlin API accounts, see perform bulk operations in the Azure Cosmos DB Gremlin API.

Prerequisites

- If you don't already have Visual Studio 2019 installed, you can download and use the Visual Studio 2019 Community Edition. Make sure that you enable "Azure development" during the Visual Studio setup.
- If you don't have an Azure subscription, create a free account before you begin.
- You can Try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments. Or, you can use the Azure Cosmos DB Emulator with the `https://localhost:8081` endpoint. The Primary Key is provided in Authenticating requests.
- Create an Azure Cosmos DB SQL API account by using the steps described in create database account section of the .NET quickstart article.

Clone the sample application

Now let's switch to working with code by downloading a sample .NET application from GitHub. This application performs bulk operations on the data stored in your Azure Cosmos account. To clone the application, open a command prompt, navigate to the directory where you want to copy it and run the following command:

```
git clone https://github.com/Azure/azure-cosmosdb-bulkexecutor-dotnet-getting-started.git
```

The cloned repository contains two samples "BulkImportSample" and "BulkUpdateSample". You can open either of the sample applications, update the connection strings in App.config file with your Azure Cosmos DB account's connection strings, build the solution, and run it.

The "BulkImportSample" application generates random documents and bulk imports them to your Azure Cosmos account. The "BulkUpdateSample" application bulk updates the imported documents by specifying patches as operations to perform on specific document fields. In the next sections, you will review the code in each of these sample apps.

Bulk import data to an Azure Cosmos account

1. Navigate to the "BulkImportSample" folder and open the "BulkImportSample.sln" file.

2. The Azure Cosmos DB's connection strings are retrieved from the App.config file as shown in the following code:

   ```
   private static readonly string EndpointUrl = ConfigurationManager.AppSettings["EndPointUrl"];
   private static readonly string AuthorizationKey = ConfigurationManager.AppSettings["AuthorizationKey"];
   private static readonly string DatabaseName = ConfigurationManager.AppSettings["DatabaseName"];
   private static readonly string CollectionName = ConfigurationManager.AppSettings["CollectionName"];
   private static readonly int CollectionThroughput =
   int.Parse(ConfigurationManager.AppSettings["CollectionThroughput"]);
   ```

   The bulk importer creates a new database and a container with the database name, container name, and the throughput values specified in the App.config file.

3. Next the DocumentClient object is initialized with Direct TCP connection mode:

   ```
   ConnectionPolicy connectionPolicy = new ConnectionPolicy
   {
      ConnectionMode = ConnectionMode.Direct,
      ConnectionProtocol = Protocol.Tcp
   };
   DocumentClient client = new DocumentClient(new Uri(endpointUrl),authorizationKey,
   connectionPolicy)
   ```

4. The BulkExecutor object is initialized with a high retry value for wait time and throttled requests. And then they are set to 0 to pass congestion control to BulkExecutor for its lifetime.

   ```
   // Set retry options high during initialization (default values).
   client.ConnectionPolicy.RetryOptions.MaxRetryWaitTimeInSeconds = 30;
   client.ConnectionPolicy.RetryOptions.MaxRetryAttemptsOnThrottledRequests = 9;

   IBulkExecutor bulkExecutor = new BulkExecutor(client, dataCollection);
   await bulkExecutor.InitializeAsync();

   // Set retries to 0 to pass complete control to bulk executor.
   client.ConnectionPolicy.RetryOptions.MaxRetryWaitTimeInSeconds = 0;
   client.ConnectionPolicy.RetryOptions.MaxRetryAttemptsOnThrottledRequests = 0;
   ```

5. The application invokes the BulkImportAsync API. The .NET library provides two overloads of the bulk import API - one that accepts a list of serialized JSON documents and the other that accepts a list of deserialized POCO documents. To learn more about the definitions of each of these overloaded methods, refer to the API documentation.

```
BulkImportResponse bulkImportResponse = await bulkExecutor.BulkImportAsync(
  documents: documentsToImportInBatch,
  enableUpsert: true,
  disableAutomaticIdGeneration: true,
  maxConcurrencyPerPartitionKeyRange: null,
  maxInMemorySortingBatchSize: null,
  cancellationToken: token);
```

BulkImportAsync method accepts the following parameters:

PARAMETER	DESCRIPTION
enableUpsert	A flag to enable upsert operations on the documents. If a document with the given ID already exists, it's updated. By default, it is set to false.
disableAutomaticIdGeneration	A flag to disable automatic generation of ID. By default, it is set to true.
maxConcurrencyPerPartitionKeyRange	The maximum degree of concurrency per partition key range, setting to null will cause library to use a default value of 20.
maxInMemorySortingBatchSize	The maximum number of documents that are pulled from the document enumerator, which is passed to the API call in each stage. For in-memory sorting phase that happens before bulk importing, setting this parameter to null will cause library to use default minimum value (documents.count, 1000000).
cancellationToken	The cancellation token to gracefully exit the bulk import operation.

Bulk import response object definition The result of the bulk import API call contains the following attributes:

PARAMETER	DESCRIPTION
NumberOfDocumentsImported (long)	The total number of documents that were successfully imported out of the total documents supplied to the bulk import API call.
TotalRequestUnitsConsumed (double)	The total request units (RU) consumed by the bulk import API call.
TotalTimeTaken (TimeSpan)	The total time taken by the bulk import API call to complete the execution.
BadInputDocuments (List<object>)	The list of bad-format documents that were not successfully imported in the bulk import API call. Fix the documents returned and retry import. Bad-formatted documents include documents whose ID value is not a string (null or any other datatype is considered invalid).

Bulk update data in your Azure Cosmos account

You can update existing documents by using the BulkUpdateAsync API. In this example, you will set the `Name` field

to a new value and remove the `Description` field from the existing documents. For the full set of supported update operations, refer to the API documentation.

1. Navigate to the "BulkUpdateSample" folder and open the "BulkUpdateSample.sln" file.

2. Define the update items along with the corresponding field update operations. In this example, you will use `SetUpdateOperation` to update the `Name` field and `UnsetUpdateOperation` to remove the `Description` field from all the documents. You can also perform other operations like increment a document field by a specific value, push specific values into an array field, or remove a specific value from an array field. To learn about different methods provided by the bulk update API, refer to the API documentation.

```
SetUpdateOperation<string> nameUpdate = new SetUpdateOperation<string>("Name", "UpdatedDoc");
UnsetUpdateOperation descriptionUpdate = new UnsetUpdateOperation("description");

List<UpdateOperation> updateOperations = new List<UpdateOperation>();
updateOperations.Add(nameUpdate);
updateOperations.Add(descriptionUpdate);

List<UpdateItem> updateItems = new List<UpdateItem>();
for (int i = 0; i < 10; i++)
{
 updateItems.Add(new UpdateItem(i.ToString(), i.ToString(), updateOperations));
}
```

3. The application invokes the BulkUpdateAsync API. To learn about the definition of the BulkUpdateAsync method, refer to the API documentation.

```
BulkUpdateResponse bulkUpdateResponse = await bulkExecutor.BulkUpdateAsync(
  updateItems: updateItems,
  maxConcurrencyPerPartitionKeyRange: null,
  maxInMemorySortingBatchSize: null,
  cancellationToken: token);
```

BulkUpdateAsync method accepts the following parameters:

PARAMETER	DESCRIPTION
maxConcurrencyPerPartitionKeyRange	The maximum degree of concurrency per partition key range, setting this parameter to null will make the library to use the default value(20).
maxInMemorySortingBatchSize	The maximum number of update items pulled from the update items enumerator passed to the API call in each stage. For the in-memory sorting phase that happens before bulk updating, setting this parameter to null will cause the library to use the default minimum value(updateItems.count, 1000000).
cancellationToken	The cancellation token to gracefully exit the bulk update operation.

Bulk update response object definition The result of the bulk update API call contains the following attributes:

PARAMETER	DESCRIPTION

PARAMETER	DESCRIPTION
NumberOfDocumentsUpdated (long)	The number of documents that were successfully updated out of the total documents supplied to the bulk update API call.
TotalRequestUnitsConsumed (double)	The total request units (RUs) consumed by the bulk update API call.
TotalTimeTaken (TimeSpan)	The total time taken by the bulk update API call to complete the execution.

Performance tips

Consider the following points for better performance when using the bulk executor library:

- For best performance, run your application from an Azure virtual machine that is in the same region as your Azure Cosmos account's write region.
- It is recommended that you instantiate a single `BulkExecutor` object for the whole application within a single virtual machine that corresponds to a specific Azure Cosmos container.
- Since a single bulk operation API execution consumes a large chunk of the client machine's CPU and network IO (This happens by spawning multiple tasks internally). Avoid spawning multiple concurrent tasks within your application process that execute bulk operation API calls. If a single bulk operation API call that is running on a single virtual machine is unable to consume the entire container's throughput (if your container's throughput > 1 million RU/s), it's preferred to create separate virtual machines to concurrently execute the bulk operation API calls.
- Ensure the `InitializeAsync()` method is invoked after instantiating a BulkExecutor object to fetch the target Cosmos container's partition map.
- In your application's App.Config, ensure **`gcServer`** is enabled for better performance

```
<runtime>
  <gcServer enabled="true" />
</runtime>
```

- The library emits traces that can be collected either into a log file or on the console. To enable both, add the following code to your application's App.Config file.

```
<system.diagnostics>
  <trace autoflush="false" indentsize="4">
    <listeners>
      <add name="logListener" type="System.Diagnostics.TextWriterTraceListener"
initializeData="application.log" />
      <add name="consoleListener" type="System.Diagnostics.ConsoleTraceListener" />
    </listeners>
  </trace>
</system.diagnostics>
```

Next steps

Migrate from the bulk executor library to the bulk support in Azure Cosmos DB .NET V3 SDK

12/4/2020 • 4 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes the required steps to migrate an existing application's code that uses the .NET bulk executor library to the bulk support feature in the latest version of the .NET SDK.

Enable bulk support

Enable bulk support on the `CosmosClient` instance through the AllowBulkExecution configuration:

```
new CosmosClient(endpoint, authKey, new CosmosClientOptions() { AllowBulkExecution = true });
```

Create Tasks for each operation

Bulk support in the .NET SDK works by leveraging the Task Parallel Library and grouping operations that occur concurrently.

There is no single method in the SDK that will take your list of documents or operations as an input parameter, but rather, you need to create a Task for each operation you want to execute in bulk, and then simply wait for them to complete.

For example, if your initial input is a list of items where each item has the following schema:

```
public class MyItem
{
    public string id { get; set; }

    public string pk { get; set; }

    public int operationCounter { get; set; } = 0;
}
```

If you want to do bulk import (similar to using BulkExecutor.BulkImportAsync), you need to have concurrent calls to `CreateItemAsync`. For example:

```
BulkOperations<MyItem> bulkOperations = new BulkOperations<MyItem>(documentsToWorkWith.Count);
foreach (MyItem document in documentsToWorkWith)
{
    bulkOperations.Tasks.Add(container.CreateItemAsync(document, new
PartitionKey(document.pk)).CaptureOperationResponse(document));
}
```

If you want to do bulk *update* (similar to using BulkExecutor.BulkUpdateAsync), you need to have concurrent calls to `ReplaceItemAsync` method after updating the item value. For example:

```
BulkOperations<MyItem> bulkOperations = new BulkOperations<MyItem>(documentsToWorkWith.Count);
foreach (MyItem document in documentsToWorkWith)
{
    document.operationCounter++;
    bulkOperations.Tasks.Add(container.ReplaceItemAsync(document, document.id, new
PartitionKey(document.pk)).CaptureOperationResponse(document));
}
```

And if you want to do bulk *delete* (similar to using BulkExecutor.BulkDeleteAsync), you need to have concurrent calls to `DeleteItemAsync`, with the `id` and partition key of each item. For example:

```
BulkOperations<MyItem> bulkOperations = new BulkOperations<MyItem>(documentsToWorkWith.Count);
foreach (MyItem document in documentsToWorkWith)
{
    document.operationCounter++;
    bulkOperations.Tasks.Add(container.DeleteItemAsync<MyItem>(document.id, new
PartitionKey(document.pk)).CaptureOperationResponse(document));
}
```

Capture task result state

In the previous code examples, we have created a concurrent list of tasks, and called the `CaptureOperationResponse` method on each of those tasks. This method is an extension that lets us maintain a *similar response schema* as BulkExecutor, by capturing any errors and tracking the request units usage.

```
public static Task<OperationResponse<T>> CaptureOperationResponse<T>(this Task<ItemResponse<T>> task, T item)
{
    return task.ContinueWith(itemResponse =>
    {
        if (itemResponse.IsCompletedSuccessfully)
        {
            return new OperationResponse<T>()
            {
                Item = item,
                IsSuccessful = true,
                RequestUnitsConsumed = task.Result.RequestCharge
            };
        }

        AggregateException innerExceptions = itemResponse.Exception.Flatten();
        if (innerExceptions.InnerExceptions.FirstOrDefault(innerEx => innerEx is CosmosException) is
CosmosException cosmosException)
        {
            return new OperationResponse<T>()
            {
                Item = item,
                RequestUnitsConsumed = cosmosException.RequestCharge,
                IsSuccessful = false,
                CosmosException = cosmosException
            };
        }

        return new OperationResponse<T>()
        {
            Item = item,
            IsSuccessful = false,
            CosmosException = innerExceptions.InnerExceptions.FirstOrDefault()
        };
    });
}
```

Where the `OperationResponse` is declared as:

```
public class OperationResponse<T>
{
    public T Item { get; set; }
    public double RequestUnitsConsumed { get; set; } = 0;
    public bool IsSuccessful { get; set; }
    public Exception CosmosException { get; set; }
}
```

Execute operations concurrently

To track the scope of the entire list of Tasks, we use this helper class:

```
public class BulkOperations<T>
{
    public readonly List<Task<OperationResponse<T>>> Tasks;

    private readonly Stopwatch stopwatch = Stopwatch.StartNew();

    public BulkOperations(int operationCount)
    {
        this.Tasks = new List<Task<OperationResponse<T>>>(operationCount);
    }

    public async Task<BulkOperationResponse<T>> ExecuteAsync()
    {
        await Task.WhenAll(this.Tasks);
        this.stopwatch.Stop();
        return new BulkOperationResponse<T>()
        {
            TotalTimeTaken = this.stopwatch.Elapsed,
            TotalRequestUnitsConsumed = this.Tasks.Sum(task => task.Result.RequestUnitsConsumed),
            SuccessfulDocuments = this.Tasks.Count(task => task.Result.IsSuccessful),
            Failures = this.Tasks.Where(task => !task.Result.IsSuccessful).Select(task => (task.Result.Item,
task.Result.CosmosException)).ToList()
        };
    }
}
```

The `ExecuteAsync` method will wait until all operations are completed and you can use it like so:

```
BulkOperationResponse<MyItem> bulkOperationResponse = await bulkOperations.ExecuteAsync();
```

Capture statistics

The previous code waits until all operations are completed and calculates the required statistics. These statistics are similar to that of the bulk executor library's BulkImportResponse.

```
public class BulkOperationResponse<T>
{
    public TimeSpan TotalTimeTaken { get; set; }
    public int SuccessfulDocuments { get; set; } = 0;
    public double TotalRequestUnitsConsumed { get; set; } = 0;

    public IReadOnlyList<(T, Exception)> Failures { get; set; }
}
```

The `BulkOperationResponse` contains:

1. The total time taken to process the list of operations through bulk support.
2. The number of successful operations.
3. The total of request units consumed.
4. If there are failures, it displays a list of tuples that contain the exception and the associated item for logging and identification purpose.

Retry configuration

Bulk executor library had guidance that mentioned to set the `MaxRetryWaitTimeInSeconds` and `MaxRetryAttemptsOnThrottledRequests` of RetryOptions to `0` to delegate control to the library.

For bulk support in the .NET SDK, there is no hidden behavior. You can configure the retry options directly through the CosmosClientOptions.MaxRetryAttemptsOnRateLimitedRequests and CosmosClientOptions.MaxRetryWaitTimeOnRateLimitedRequests.

> **NOTE**
> In cases where the provisioned request units is much lower than the expected based on the amount of data, you might want to consider setting these to high values. The bulk operation will take longer but it has a higher chance of completely succeeding due to the higher retries.

Performance improvements

As with other operations with the .NET SDK, using the stream APIs results in better performance and avoids any unnecessary serialization.

Using stream APIs is only possible if the nature of the data you use matches that of a stream of bytes (for example, file streams). In such cases, using the `CreateItemStreamAsync`, `ReplaceItemStreamAsync`, or `DeleteItemStreamAsync` methods and working with `ResponseMessage` (instead of `ItemResponse`) increases the throughput that can be achieved.

Next steps

Use bulk executor Java library to perform bulk operations on Azure Cosmos DB data

11/2/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

This tutorial provides instructions on using the Azure Cosmos DB's bulk executor Java library to import, and update Azure Cosmos DB documents. To learn about bulk executor library and how it helps you leverage massive throughput and storage, see bulk executor Library overview article. In this tutorial, you build a Java application that generates random documents and they are bulk imported into an Azure Cosmos container. After importing, you will bulk update some properties of a document.

Currently, the bulk executor library is supported only by Azure Cosmos DB SQL API and Gremlin API accounts. This article describes how to use bulk executor Java library with SQL API accounts. To learn about using bulk executor .NET library with Gremlin API, see perform bulk operations in Azure Cosmos DB Gremlin API. The bulk executor library described is available is only available for the Azure Cosmos DB Java sync SDK v2 and it is the current recommended solution for Java bulk support. It is currently not available for the 3.x, 4.x or other higher SDK versions.

Prerequisites

- If you don't have an Azure subscription, create a free account before you begin.
- You can try Azure Cosmos DB for free without an Azure subscription, free of charge and commitments. Or, you can use the Azure Cosmos DB Emulator with the `https://localhost:8081` endpoint. The Primary Key is provided in Authenticating requests.
- Java Development Kit (JDK) 1.7+
  - On Ubuntu, run `apt-get install default-jdk` to install the JDK.
  - Be sure to set the JAVA_HOME environment variable to point to the folder where the JDK is installed.
- Download and install a Maven binary archive
  - On Ubuntu, you can run `apt-get install maven` to install Maven.
- Create an Azure Cosmos DB SQL API account by using the steps described in the create database account section of the Java quickstart article.

Clone the sample application

Now let's switch to working with code by downloading a sample Java application from GitHub. This application performs bulk operations on Azure Cosmos DB data. To clone the application, open a command prompt, navigate to the directory where you want to copy the application and run the following command:

```
git clone https://github.com/Azure/azure-cosmosdb-bulkexecutor-java-getting-started.git
```

The cloned repository contains two samples "bulkimport" and "bulkupdate" relative to the "\azure-cosmosdb-bulkexecutor-java-getting-started\samples\bulkexecutor-sample\src\main\java\com\microsoft\azure\cosmosdb\bulkexecutor" folder. The "bulkimport" application generates random documents and imports them to Azure Cosmos DB. The "bulkupdate" application updates some

documents in Azure Cosmos DB. In the next sections, we will review the code in each of these sample apps.

Bulk import data to Azure Cosmos DB

1. The Azure Cosmos DB's connection strings are read as arguments and assigned to variables defined in CmdLineConfiguration.java file.

2. Next the DocumentClient object is initialized by using the following statements:

```
ConnectionPolicy connectionPolicy = new ConnectionPolicy();
connectionPolicy.setMaxPoolSize(1000);
DocumentClient client = new DocumentClient(
   HOST,
   MASTER_KEY,
   connectionPolicy,
   ConsistencyLevel.Session)
```

3. The DocumentBulkExecutor object is initialized with a high retry values for wait time and throttled requests. And then they are set to 0 to pass congestion control to DocumentBulkExecutor for its lifetime.

```
// Set client's retry options high for initialization
client.getConnectionPolicy().getRetryOptions().setMaxRetryWaitTimeInSeconds(30);
client.getConnectionPolicy().getRetryOptions().setMaxRetryAttemptsOnThrottledRequests(9);

// Builder pattern
Builder bulkExecutorBuilder = DocumentBulkExecutor.builder().from(
  client,
  DATABASE_NAME,
  COLLECTION_NAME,
  collection.getPartitionKey(),
  offerThroughput) // throughput you want to allocate for bulk import out of the container's total
throughput

// Instantiate DocumentBulkExecutor
DocumentBulkExecutor bulkExecutor = bulkExecutorBuilder.build()

// Set retries to 0 to pass complete control to bulk executor
client.getConnectionPolicy().getRetryOptions().setMaxRetryWaitTimeInSeconds(0);
client.getConnectionPolicy().getRetryOptions().setMaxRetryAttemptsOnThrottledRequests(0);
```

4. Call the importAll API that generates random documents to bulk import into an Azure Cosmos container. You can configure the command line configurations within the CmdLineConfiguration.java file.

```
BulkImportResponse bulkImportResponse = bulkExecutor.importAll(documents, false, true, null);
```

The bulk import API accepts a collection of JSON-serialized documents and it has the following syntax, for more details, see the API documentation:

```
public BulkImportResponse importAll(
     Collection<String> documents,
     boolean isUpsert,
     boolean disableAutomaticIdGeneration,
     Integer maxConcurrencyPerPartitionRange) throws DocumentClientException;
```

The importAll method accepts the following parameters:

PARAMETER	DESCRIPTION
isUpsert	A flag to enable upsert of the documents. If a document with given ID already exists, it's updated.
disableAutomaticIdGeneration	A flag to disable automatic generation of ID. By default, it is set to true.
maxConcurrencyPerPartitionRange	The maximum degree of concurrency per partition key range. The default value is 20.

Bulk import response object definition The result of the bulk import API call contains the following get methods:

PARAMETER	DESCRIPTION
int getNumberOfDocumentsImported()	The total number of documents that were successfully imported out of the documents supplied to the bulk import API call.
double getTotalRequestUnitsConsumed()	The total request units (RU) consumed by the bulk import API call.
Duration getTotalTimeTaken()	The total time taken by the bulk import API call to complete execution.
List<Exception> getErrors()	Gets the list of errors if some documents out of the batch supplied to the bulk import API call failed to get inserted.
List<Object> getBadInputDocuments()	The list of bad-format documents that were not successfully imported in the bulk import API call. User should fix the documents returned and retry import. Bad-formatted documents include documents whose ID value is not a string (null or any other datatype is considered invalid).

5. After you have the bulk import application ready, build the command-line tool from source by using the 'mvn clean package' command. This command generates a jar file in the target folder:

```
mvn clean package
```

6. After the target dependencies are generated, you can invoke the bulk importer application by using the following command:

```
java -Xmx12G -jar bulkexecutor-sample-1.0-SNAPSHOT-jar-with-dependencies.jar -serviceEndpoint *<Fill in
your Azure Cosmos DB's endpoint>*  -masterKey *<Fill in your Azure Cosmos DB's primary key>* -
databaseId bulkImportDb -collectionId bulkImportColl -operation import -shouldCreateCollection -
collectionThroughput 1000000 -partitionKey /profileid -maxConnectionPoolSize 6000 -
numberOfDocumentsForEachCheckpoint 1000000 -numberOfCheckpoints 10
```

The bulk importer creates a new database and a collection with the database name, collection name, and throughput values specified in the App.config file.

Bulk update data in Azure Cosmos DB

You can update existing documents by using the BulkUpdateAsync API. In this example, you will set the Name field to a new value and remove the Description field from the existing documents. For the full set of supported field update operations, see API documentation.

1. Defines the update items along with corresponding field update operations. In this example, you will use SetUpdateOperation to update the Name field and UnsetUpdateOperation to remove the Description field from all the documents. You can also perform other operations like increment a document field by a specific value, push specific values into an array field, or remove a specific value from an array field. To learn about different methods provided by the bulk update API, see the API documentation.

```
SetUpdateOperation<String> nameUpdate = new SetUpdateOperation<>("Name","UpdatedDocValue");
UnsetUpdateOperation descriptionUpdate = new UnsetUpdateOperation("description");

ArrayList<UpdateOperationBase> updateOperations = new ArrayList<>();
updateOperations.add(nameUpdate);
updateOperations.add(descriptionUpdate);

List<UpdateItem> updateItems = new ArrayList<>(cfg.getNumberOfDocumentsForEachCheckpoint());
IntStream.range(0, cfg.getNumberOfDocumentsForEachCheckpoint()).mapToObj(j -> {
 return new UpdateItem(Long.toString(prefix + j), Long.toString(prefix + j), updateOperations);
 }).collect(Collectors.toCollection(() -> updateItems));
```

2. Call the updateAll API that generates random documents to be then bulk imported into an Azure Cosmos container. You can configure the command-line configurations to be passed in CmdLineConfiguration.java file.

```
BulkUpdateResponse bulkUpdateResponse = bulkExecutor.updateAll(updateItems, null)
```

The bulk update API accepts a collection of items to be updated. Each update item specifies the list of field update operations to be performed on a document identified by an ID and a partition key value. for more details, see the API documentation:

```
public BulkUpdateResponse updateAll(
     Collection<UpdateItem> updateItems,
     Integer maxConcurrencyPerPartitionRange) throws DocumentClientException;
```

The updateAll method accepts the following parameters:

PARAMETER	DESCRIPTION
maxConcurrencyPerPartitionRange	The maximum degree of concurrency per partition key range. The default value is 20.

Bulk import response object definition The result of the bulk import API call contains the following get methods:

PARAMETER	DESCRIPTION
int getNumberOfDocumentsUpdated()	The total number of documents that were successfully updated out of the documents supplied to the bulk update API call.
double getTotalRequestUnitsConsumed()	The total request units (RU) consumed by the bulk update API call.

PARAMETER	DESCRIPTION
Duration getTotalTimeTaken()	The total time taken by the bulk update API call to complete execution.
List<Exception> getErrors()	Gets the list of operational or networking issues related to the update operation.
List<BulkUpdateFailure> getFailedUpdates()	Gets the list of updates which could not be completed along with the specific exceptions leading to the failures.

3. After you have the bulk update application ready, build the command-line tool from source by using the 'mvn clean package' command. This command generates a jar file in the target folder:

```
mvn clean package
```

4. After the target dependencies are generated, you can invoke the bulk update application by using the following command:

```
java -Xmx12G -jar bulkexecutor-sample-1.0-SNAPSHOT-jar-with-dependencies.jar -serviceEndpoint **<Fill
in your Azure Cosmos DB's endpoint>* -masterKey **<Fill in your Azure Cosmos DB's primary key>* -
databaseId bulkUpdateDb -collectionId bulkUpdateColl -operation update -collectionThroughput 1000000 -
partitionKey /profileid -maxConnectionPoolSize 6000 -numberOfDocumentsForEachCheckpoint 1000000 -
numberOfCheckpoints 10
```

Performance tips

Consider the following points for better performance when using bulk executor library:

- For best performance, run your application from an Azure VM in the same region as your Cosmos DB account write region.
- For achieving higher throughput:
  - Set the JVM's heap size to a large enough number to avoid any memory issue in handling large number of documents. Suggested heap size: max(3GB, 3 * sizeof(all documents passed to bulk import API in one batch)).
  - There is a preprocessing time, due to which you will get higher throughput when performing bulk operations with a large number of documents. So, if you want to import 10,000,000 documents, running bulk import 10 times on 10 bulk of documents each of size 1,000,000 is preferable than running bulk import 100 times on 100 bulk of documents each of size 100,000 documents.
- It is recommended to instantiate a single DocumentBulkExecutor object for the entire application within a single virtual machine that corresponds to a specific Azure Cosmos container.
- Since a single bulk operation API execution consumes a large chunk of the client machine's CPU and network IO. This happens by spawning multiple tasks internally, avoid spawning multiple concurrent tasks within your application process each executing bulk operation API calls. If a single bulk operation API call running on a single virtual machine is unable to consume your entire container's throughput (if your container's throughput > 1 million RU/s), it's preferable to create separate virtual machines to concurrently execute bulk operation API calls.

Visualize Azure Cosmos DB data by using the Power BI connector

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

Power BI is an online service where you can create and share dashboards and reports. Power BI Desktop is a report authoring tool that enables you to retrieve data from various data sources. Azure Cosmos DB is one of the data source that you can use with Power BI Desktop. You can connect Power BI Desktop to Azure Cosmos DB account with the Azure Cosmos DB connector for Power BI. After you import Azure Cosmos DB data to Power BI, you can transform it, create reports, and publish the reports to Power BI.

This article describes the steps required to connect Azure Cosmos DB account to Power BI Desktop. After connecting, you navigate to a collection, extract the data, transform the JSON data into tabular format, and publish a report to Power BI.

> **NOTE**
> The Power BI connector for Azure Cosmos DB connects to Power BI Desktop. Reports created in Power BI Desktop can be published to PowerBI.com. Direct extraction of Azure Cosmos DB data cannot be performed from PowerBI.com.

> **NOTE**
> Connecting to Azure Cosmos DB with the Power BI connector is currently supported for Azure Cosmos DB SQL API and Gremlin API accounts only.

Prerequisites

Before following the instructions in this Power BI tutorial, ensure that you have access to the following resources:

- Download the latest version of Power BI Desktop.
- Download the sample volcano data from GitHub.
- Create an Azure Cosmos database account and import the volcano data by using the Azure Cosmos DB data migration tool. When importing data, consider the following settings for the source and destinations in the data migration tool:
  - **Source parameters**
    - **Import from:** JSON file(s)
  - **Target parameters**
    - **Connection string:**
      ```
      AccountEndpoint=<Your_account_endpoint>;AccountKey=
      <Your_primary_or_secondary_key>;Database= <Your_database_name>
      ```
    - **Partition key:** /Country
    - **Collection Throughput:** 1000

To share your reports in PowerBI.com, you must have an account in PowerBI.com. To learn more about Power BI

and Power BI Pro, see https://powerbi.microsoft.com/pricing.

Let's get started

In this tutorial, let's imagine that you are a geologist studying volcanoes around the world. The volcano data is stored in an Azure Cosmos DB account and the JSON document format is as follows:

```
{
    "Volcano Name": "Rainier",
        "Country": "United States",
        "Region": "US-Washington",
        "Location": {
          "type": "Point",
          "coordinates": [
            -121.758,
            46.87
          ]
        },
        "Elevation": 4392,
        "Type": "Stratovolcano",
        "Status": "Dendrochronology",
        "Last Known Eruption": "Last known eruption from 1800-1899, inclusive"
}
```

You will retrieve the volcano data from the Azure Cosmos DB account and visualize data in an interactive Power BI report.

1. Run Power BI Desktop.

2. You can **Get Data**, see **Recent Sources**, or **Open Other Reports** directly from the welcome screen. Select the "X" at the top right corner to close the screen. The **Report** view of Power BI Desktop is displayed.

3. Select the **Home** ribbon, then click on **Get Data**. The **Get Data** window should appear.

4. Click on **Azure**, select **Azure Cosmos DB (Beta)**, and then click **Connect**.

5. On the **Preview Connector** page, click **Continue**. The **Azure Cosmos DB** window appears.

6. Specify the Azure Cosmos DB account endpoint URL you would like to retrieve the data from as shown below, and then click **OK**. To use your own account, you can retrieve the URL from the URI box in the **Keys** blade of the Azure portal. Optionally you can provide the database name, collection name or use the navigator to select the database and collection to identify where the data comes from.

7. If you are connecting to this endpoint for the first time, you are prompted for the account key. For your own account, retrieve the key from the **Primary Key** box in the **Read-only Keys** blade of the Azure portal. Enter the appropriate key and then click **Connect**.

   We recommend that you use the read-only key when building reports. This prevents unnecessary exposure of the primary key to potential security risks. The read-only key is available from the **Keys** blade of the Azure portal.

8. When the account is successfully connected, the **Navigator** pane appears. The **Navigator** shows a list of databases under the account.

9. Click and expand on the database where the data for the report comes from, select **volcanodb** (your database name can be different).

10. Now, select a collection that contains the data to retrieve, select **volcano1** (your collection name can be different).

    The Preview pane shows a list of **Record** items. A Document is represented as a **Record** type in Power BI. Similarly, a nested JSON block inside a document is also a **Record**.

11. Click **Edit** to launch the Query Editor in a new window to transform the data.

Flattening and transforming JSON documents

1. Switch to the Power BI Query Editor window, where the **Document** column in the center pane.

2. Click on the expander at the right side of the **Document** column header. The context menu with a list of fields will appear. Select the fields you need for your report, for instance, Volcano Name, Country, Region, Location, Elevation, Type, Status and Last Know Eruption. Uncheck the **Use original column name as prefix** box, and then click **OK**.

3. The center pane displays a preview of the result with the fields selected.

4. In our example, the Location property is a GeoJSON block in a document. As you can see, Location is represented as a **Record** type in Power BI Desktop.

5. Click on the expander at the right side of the Document.Location column header. The context menu with type and coordinates fields appear. Let's select the coordinates field, ensure **Use original column name as prefix** is not selected, and click **OK**.

6. The center pane now shows a coordinates column of **List** type. As shown at the beginning of the tutorial, the GeoJSON data in this tutorial is of Point type with Latitude and Longitude values recorded in the coordinates array.

   The coordinates[0] element represents Longitude while coordinates[1] represents Latitude.

7. To flatten the coordinates array, create a **Custom Column** called LatLong. Select the **Add Column** ribbon and click on **Custom Column**. The **Custom Column** window appears.

8. Provide a name for the new column, e.g. LatLong.

9. Next, specify the custom formula for the new column. For our example, we will concatenate the Latitude and Longitude values separated by a comma as shown below using the following formula: `Text.From([coordinates]{1})&","&Text.From([coordinates]{0})`. Click **OK**.

   For more information on Data Analysis Expressions (DAX) including DAX functions, please visit DAX Basics in Power BI Desktop.

10. Now, the center pane shows the new LatLong columns populated with the values.

If you receive an Error in the new column, make sure that the applied steps under Query Settings match the following figure:

If your steps are different, delete the extra steps and try adding the custom column again.

11. Click **Close and Apply** to save the data model.

Build the reports

Power BI Desktop Report view is where you can start creating reports to visualize data. You can create reports by dragging and dropping fields into the **Report** canvas.

In the Report view, you should find:

1. The **Fields** pane, this is where you can see a list of data models with fields you can use for your reports.
2. The **Visualizations** pane. A report can contain a single or multiple visualizations. Pick the visual types fitting your needs from the **Visualizations** pane.
3. The **Report** canvas, this is where you build the visuals for your report.
4. The **Report** page. You can add multiple report pages in Power BI Desktop.

The following shows the basic steps of creating a simple interactive Map view report.

1. For our example, we will create a map view showing the location of each volcano. In the **Visualizations** pane, click on the Map visual type as highlighted in the screenshot above. You should see the Map visual type painted on the **Report** canvas. The **Visualization** pane should also display a set of properties related to the Map visual type.

2. Now, drag and drop the LatLong field from the **Fields** pane to the **Location** property in **Visualizations** pane.

3. Next, drag and drop the Volcano Name field to the **Legend** property.

4. Then, drag and drop the Elevation field to the **Size** property.

5. You should now see the Map visual showing a set of bubbles indicating the location of each volcano with the size of the bubble correlating to the elevation of the volcano.

6. You now have created a basic report. You can further customize the report by adding more visualizations. In our case, we added a Volcano Type slicer to make the report interactive.

7. On the File menu, click **Save** and save the file as PowerBITutorial.pbix.

Publish and share your report

To share your report, you must have an account in PowerBI.com.

1. In the Power BI Desktop, click on the **Home** ribbon.

2. Click **Publish**. You are be prompted to enter the user name and password for your PowerBI.com account.

3. Once the credential has been authenticated, the report is published to your destination you selected.

4. Click **Open 'PowerBITutorial.pbix' in Power BI** to see and share your report on PowerBI.com.

Create a dashboard in PowerBI.com

Now that you have a report, lets share it on PowerBI.com

When you publish your report from Power BI Desktop to PowerBI.com, it generates a **Report** and a **Dataset** in your PowerBI.com tenant. For example, after you published a report called **PowerBITutorial** to PowerBI.com, you will see PowerBITutorial in both the **Reports** and **Datasets** sections on PowerBI.com.

To create a sharable dashboard, click the **Pin Live Page** button on your PowerBI.com report.

Then follow the instructions in Pin a tile from a report to create a new dashboard.

You can also do ad hoc modifications to report before creating a dashboard. However, it's recommended that you use Power BI Desktop to perform the modifications and republish the report to PowerBI.com.

Next steps

- To learn more about Power BI, see Get started with Power BI.
- To learn more about Azure Cosmos DB, see the Azure Cosmos DB documentation landing page.

Create a real-time dashboard using Azure Cosmos DB and Power BI

12/4/2020 • 7 minutes to read • Edit Online

APPLIES TO: SQL API

This article describes the steps required to create a live weather dashboard in Power BI using Azure Cosmos DB and Azure Analysis Services. The Power BI dashboard will display charts to show real-time information about temperature and rainfall in a region.

Reporting scenarios

There are multiple ways to set up reporting dashboards on data stored in Azure Cosmos DB. Depending on the staleness requirements and the size of the data, the following table describes the reporting setup for each scenario:

SCENARIO	SETUP
1. Generating ad-hoc reports (no refresh)	Power BI Azure Cosmos DB connector with import mode
2. Generating ad-hoc reports with periodic refresh	Power BI Azure Cosmos DB connector with import mode (Scheduled periodic refresh)
3. Reporting on large data sets (< 10 GB)	Power BI Azure Cosmos DB connector with incremental refresh
4. Reporting real time on large data sets	Power BI Azure Analysis Services connector with direct query + Azure Analysis Services (Azure Cosmos DB connector)
5. Reporting on live data with aggregates	Power BI Spark connector with direct query + Azure Databricks + Cosmos DB Spark connector.
6. Reporting on live data with aggregates on large data sets	Power BI Azure Analysis Services connector with direct query + Azure Analysis Services + Azure Databricks + Cosmos DB Spark connector.

Scenarios 1 and 2 can be easily set up using the Azure Cosmos DB Power BI connector. This article describes the setups for scenarios 3 and 4.

Power BI with incremental refresh

Power BI has a mode where incremental refresh can be configured. This mode eliminates the need to create and manage Azure Analysis Services partitions. Incremental refresh can be set up to filter only the latest updates in large datasets. However, this mode works only with Power BI Premium service that has a dataset limitation of 10 GB.

Power BI Azure Analysis connector + Azure Analysis Services

Azure Analysis Services provides a fully managed platform as a service that hosts enterprise-grade data models in the cloud. Massive data sets can be loaded from Azure Cosmos DB into Azure Analysis Services. To avoid querying the entire dataset all the time, the datasets can be subdivided into Azure Analysis Services partitions, which can be refreshed independently at different frequencies.

Power BI incremental refresh

Ingest weather data into Azure Cosmos DB

Set up an ingestion pipeline to load weather data to Azure Cosmos DB. You can set up an Azure Data Factory (ADF) job to periodically load the latest weather data into Azure Cosmos DB using the HTTP Source and Cosmos DB sink.

Connect Power BI to Azure Cosmos DB

1. **Connect Azure Cosmos account to Power BI** - Open the Power BI Desktop and use the Azure Cosmos DB connector to select the right database and container.

2. **Configure incremental refresh** - Follow the steps in incremental refresh with Power BI article to configure incremental refresh for the dataset. Add the **RangeStart** and **RangeEnd** parameters as shown in the following screenshot:

Since the dataset has a Date column that is in text form, the **RangeStart** and **RangeEnd** parameters should be transformed to use the following filter. In the **Advanced Editor** pane, modify your query add the following text to filter the rows based on the RangeStart and RangeEnd parameters:

```
#"Filtered Rows" = Table.SelectRows(#"Expanded Document", each [Document.date] >
DateTime.ToText(RangeStart,"yyyy-MM-dd") and [Document.date] < DateTime.ToText(RangeEnd,"yyyy-MM-dd"))
```

Depending on which column and data type is present in the source dataset, you can change the RangeStart and RangeEnd fields accordingly

PROPERTY	DATA TYPE	FILTER
_ts	Numeric	[_ts] > Duration.TotalSeconds(RangeStart - #datetime(1970, 1, 1, 0, 0, 0)) and [_ts] < Duration.TotalSeconds(RangeEnd - #datetime(1970, 1, 1, 0, 0, 0)))

PROPERTY	DATA TYPE	FILTER
Date (for example:- 2019-08-19)	String	[Document.date]> DateTime.ToText(RangeStart,"yyyy-MM-dd") and [Document.date] < DateTime.ToText(RangeEnd,"yyyy-MM-dd")
Date (for example:- 2019-08-11 12:00:00)	String	[Document.date]> DateTime.ToText(RangeStart," yyyy-mm-dd HH:mm:ss") and [Document.date] < DateTime.ToText(RangeEnd,"yyyy-mm-dd HH:mm:ss")

3. **Define the refresh policy** - Define the refresh policy by navigating to the **Incremental refresh** tab on the **context** menu for the table. Set the refresh policy to refresh **every day** and store the last month data.

Ignore the warning that says *the M query cannot be confirmed to be folded*. The Azure Cosmos DB connector folds filter queries.

4. **Load the data and generate the reports** - By using the data you have loaded earlier, create the charts to report on temperature and rainfall.

5. **Publish the report to Power BI premium** - Since incremental refresh is a Premium only feature, the publish dialog only allows selection of a workspace on Premium capacity. The first refresh may take longer to import the historical data. Subsequent data refreshes are much quicker because they use incremental refresh.

Power BI Azure Analysis connector + Azure Analysis Services

Ingest weather data into Azure Cosmos DB

Set up an ingestion pipeline to load weather data to Azure Cosmos DB. You can set up an Azure Data Factory(ADF) job to periodically load the latest weather data into Azure Cosmos DB using the HTTP Source and Cosmos DB Sink.

Connect Azure Analysis Services to Azure Cosmos account

1. **Create a new Azure Analysis Services cluster** - Create an instance of Azure Analysis services in the same region as the Azure Cosmos account and the Databricks cluster.

2. **Create a new Analysis Services Tabular Project in Visual Studio** - Install the SQL Server Data Tools (SSDT) and create an Analysis Services Tabular project in Visual Studio.

Choose the **Integrated Workspace** instance and the set the Compatibility Level to **SQL Server 2017 / Azure Analysis Services (1400)**

3. **Add the Azure Cosmos DB data source** - Navigate to **Models** > **Data Sources** > **New Data Source** and add the Azure Cosmos DB data source as shown in the following screenshot:

Connect to Azure Cosmos DB by providing the **account URI**, **database name**, and the **container name**. You can now see the data from Azure Cosmos container is imported into Power BI.

= Table.ExpandRecordColumn(Source, "Document",

	Document.freezingfog	Document.temperaturemax	Document.blowingsnow	Document.freezingrain	Document.rain
1	No	59	No	No	No
2	No	89.1	No	No	No
3	No	80.1	No	No	No
4	No	55	No	No	No
5	No	68	No	No	No
6	No	95	No	No	No
7	No	53.1	No	No	No
8	No	60.1	No	No	No
9	No	84	No	No	No
10	No	86	No	No	No
11	No	61	No	No	No
12	No	48	No	No	No
13	No	88	No	No	No
14	No	87.1	No	No	No
15	No	89.1	No	No	No
16	No	75.9	No	No	No
17	No	57.9	No	No	Yes

4. **Construct the Analysis Services model** - Open the query editor, perform the required operations to optimize the loaded data set:

   - Extract only the weather-related columns (temperature and rainfall)

- Extract the month information from the table. This data is useful in creating partitions as described in the next section.
- Convert the temperature columns to number

The resulting M expression is as follows:

```
 let
     Source=#"DocumentDB/https://[ACCOUNTNAME].documents.azure.com:443/",
     #"Expanded Document" = Table.ExpandRecordColumn(Source, "Document", {"id", "_rid", "_self",
"_etag", "fogground", "snowfall", "dust", "snowdepth", "mist", "drizzle", "hail",
"fastest2minwindspeed", "thunder", "glaze", "snow", "ice", "fog", "temperaturemin",
"fastest5secwindspeed", "freezingfog", "temperaturemax", "blowingsnow", "freezingrain", "rain",
"highwind", "date", "precipitation", "fogheavy", "smokehaze", "avgwindspeed", "fastest2minwinddir",
"fastest5secwinddir", "_attachments", "_ts"}, {"Document.id", "Document._rid", "Document._self",
"Document._etag", "Document.fogground", "Document.snowfall", "Document.dust", "Document.snowdepth",
"Document.mist", "Document.drizzle", "Document.hail", "Document.fastest2minwindspeed",
"Document.thunder", "Document.glaze", "Document.snow", "Document.ice", "Document.fog",
"Document.temperaturemin", "Document.fastest5secwindspeed", "Document.freezingfog",
"Document.temperaturemax", "Document.blowingsnow", "Document.freezingrain", "Document.rain",
"Document.highwind", "Document.date", "Document.precipitation", "Document.fogheavy",
"Document.smokehaze", "Document.avgwindspeed", "Document.fastest2minwinddir",
"Document.fastest5secwinddir", "Document._attachments", "Document._ts"}),
     #"Select Columns" = Table.SelectColumns(#"Expanded Document",{"Document.temperaturemin",
"Document.temperaturemax", "Document.rain", "Document.date"}),
     #"Duplicated Column" = Table.DuplicateColumn(#"Select Columns", "Document.date", "Document.month"),
     #"Extracted First Characters" = Table.TransformColumns(#"Duplicated Column", {{"Document.month",
each Text.Start(_, 7), type text}}),
     #"Sorted Rows" = Table.Sort(#"Extracted First Characters",{{"Document.date", Order.Ascending}}),
     #"Changed Type" = Table.TransformColumnTypes(#"Sorted Rows",{{"Document.temperaturemin", type
number}, {"Document.temperaturemax", type number}}),
     #"Filtered Rows" = Table.SelectRows(#"Changed Type", each [Document.month] = "2019-07")
 in
     #"Filtered Rows"
```

Additionally, change the data type of the temperature columns to Decimal to make sure that these values can be plotted in Power BI.

5. **Create Azure Analysis partitions** - Create partitions in Azure Analysis Services to divide the dataset into logical partitions that can be refreshed independently and at different frequencies. In this example, you create two partitions that would divide the dataset into the most recent month's data and everything else.

Create the following two partitions in Azure Analysis Services:

- **Latest Month** - `#"Filtered Rows" = Table.SelectRows(#"Sorted Rows", each [Document.month] = "2019-07")`
- **Historical** - `#"Filtered Rows" = Table.SelectRows(#"Sorted Rows", each [Document.month] <> "2019-07")`

6. **Deploy the Model to the Azure Analysis Server** - Right click on the Azure Analysis Services project and choose **Deploy**. Add the server name in the **Deployment Server properties** pane.

7. **Configure partition refreshes and merges** - Azure Analysis Services allows independent processing of partitions. Since we want the **Latest Month** partition to be constantly updated with the most recent data, set the refresh interval to 5 minutes. You can refresh the data by using the REST API, Azure automation, or

with a Logic App. It's not required to refresh the data in historical partition. Additionally, you need to write some code to consolidate the latest month partition to the historical partition and create a new latest month partition.

Connect Power BI to Analysis Services

1. **Connect to the Azure Analysis Server using the Azure Analysis Services database Connector** - Choose the **Live mode** and connect to the Azure Analysis Services instance as shown in the following screenshot:

2. **Load the data and generate reports** - By using the data you have loaded earlier, create charts to report on temperature and rainfall. Since you are creating a live connection, the queries should be executed on the data in the Azure Analysis Services model that you have deployed in the previous step. The temperature charts will be updated within five minutes after the new data is loaded into Azure Cosmos DB.

- To learn more about Power BI, see Get started with Power BI.
- Connect Qlik Sense to Azure Cosmos DB and visualize your data

Connect Qlik Sense to Azure Cosmos DB and visualize your data

12/4/2020 • 3 minutes to read • Edit Online

APPLIES TO: SQL API Azure Cosmos DB API for MongoDB

Qlik Sense is a data visualization tool that combines data from different sources into a single view. Qlik Sense indexes every possible relationship in your data so that you can gain immediate insights to the data. You can visualize Azure Cosmos DB data by using Qlik Sense. This article describes the steps required to connect Azure Cosmos DB to Qlik Sense and visualize your data.

> **NOTE**
> Connecting Qlik Sense to Azure Cosmos DB is currently supported for SQL API and Azure Cosmos DB's API for MongoDB accounts only.

You can Connect Qlik Sense to Azure Cosmos DB with:

- Cosmos DB SQL API by using the ODBC connector.
- Azure Cosmos DB's API for MongoDB by using the Qlik Sense MongoDB connector (currently in preview).
- Azure Cosmos DB's API for MongoDB and SQL API by using REST API connector in Qlik Sense.
- Cosmos DB Mongo DB API by using the gRPC connector for Qlik Core. This article describes the details of connecting to the Cosmos DB SQL API by using the ODBC connector.

This article describes the details of connecting to the Cosmos DB SQL API by using the ODBC connector.

Prerequisites

Before following the instructions in this article, ensure that you have the following resources ready:

- Download the Qlik Sense Desktop or set up Qlik Sense in Azure by Installing the Qlik Sense marketplace item.
- Download the video game data, this sample data is in CSV format. You will store this data in a Cosmos DB account and visualize it in Qlik Sense.
- Create an Azure Cosmos DB SQL API account by using the steps described in create an account section of the quickstart article.
- Create a database and a collection – You can use set the collection throughput value to 1000 RU/s.
- Load the sample video game sales data to your Cosmos DB account. You can import the data by using Azure Cosmos DB data migration tool, you can do a sequential or a bulk import of data. It takes around 3-5 minutes for the data to import to the Cosmos DB account.
- Download, install, and configure the ODBC driver by using the steps in the connect to Cosmos DB with ODBC driver article. The video game data is a simple data set and you don't have to edit the schema, just use the default collection-mapping schema.

Connect Qlik Sense to Cosmos DB

1. Open Qlik Sense and select **Create new app**. Provide a name for your app and select **Create**.

2. After the new app is created successfully, select **Open app** and choose **Add data from files and other sources**.

3. From the data sources, select **ODBC** to open the new connection setup window.

4. Switch to **User DSN** and choose the ODBC connection you created earlier. Provide a name for the connection and select **Create**.

5. After you create the connection, you can choose the database, collection where the video game data is located and then preview it.

6. Next select **Add data** to load the data to Qlik Sense. After you load data to Qlik Sense, you can generate insights and perform analysis on the data. You can either use the insights or build your own app exploring the video games sales. The following image shows

Limitations when connecting with ODBC

Cosmos DB is a schema-less distributed database with drivers modeled around developer needs. The ODBC driver requires a database with schema to infer columns, their data types, and other properties. The regular SQL query or the DML syntax with relational capability is not applicable to Cosmos DB SQL API because SQL API is not ANSI SQL. Due to this reason, the SQL statements issued through the ODBC driver are translated into Cosmos DB-specific SQL syntax that doesn't have equivalents for all constructs. To prevent these translation issues, you must apply a schema when setting up the ODBC connection. The connect with ODBC driver article gives you suggestions and methods to help you configure the schema. Make sure to create this mapping for every database/collection within the Cosmos DB account.

Next Steps

If you are using a different visualization tool such as Power BI, you can connect to it by using the instructions in the following doc:

- Visualize Cosmos DB data by using the Power BI connector

Accelerate big data analytics by using the Apache Spark to Azure Cosmos DB connector

12/4/2020 • 5 minutes to read • Edit Online

APPLIES TO: SQL API

You can run Spark jobs with data stored in Azure Cosmos DB using the Cosmos DB Spark connector. Cosmos can be used for batch and stream processing, and as a serving layer for low latency access.

You can use the connector with Azure Databricks or Azure HDInsight, which provide managed Spark clusters on Azure. The following table shows supported Spark versions.

COMPONENT	VERSION
Apache Spark	2.4.x, 2.3.x, 2.2.x, and 2.1.x
Scala	2.11
Azure Databricks runtime version	> 3.4

WARNING

This connector supports the core (SQL) API of Azure Cosmos DB. For Cosmos DB for MongoDB API, use the MongoDB Spark connector. For Cosmos DB Cassandra API, use the Cassandra Spark connector.

Quickstart

- Follow the steps at Get started with the Java SDK to set up a Cosmos DB account, and populate some data.
- Follow the steps at Azure Databricks getting started to set up an Azure Databricks workspace and cluster.
- You can now create new Notebooks, and import the Cosmos DB connector library. Jump to Working with the Cosmos DB connector for details on how to set up your workspace.
- The following section has snippets on how to read and write using the connector.

Batch reads from Cosmos DB

The following snippet shows how to create a Spark DataFrame to read from Cosmos DB in PySpark.

```
# Read Configuration
readConfig = {
    "Endpoint": "https://doctorwho.documents.azure.com:443/",
    "Masterkey": "YOUR-KEY-HERE",
    "Database": "DepartureDelays",
    "Collection": "flights_pcoll",
    "query_custom": "SELECT c.date, c.delay, c.distance, c.origin, c.destination FROM c WHERE c.origin =
'SEA'" // Optional
}

# Connect via azure-cosmosdb-spark to create Spark DataFrame
flights = spark.read.format(
    "com.microsoft.azure.cosmosdb.spark").options(**readConfig).load()
flights.count()
```

And the same code snippet in Scala:

```
// Import Necessary Libraries
import com.microsoft.azure.cosmosdb.spark.schema._
import com.microsoft.azure.cosmosdb.spark._
import com.microsoft.azure.cosmosdb.spark.config.Config

// Read Configuration
val readConfig = Config(Map(
  "Endpoint" -> "https://doctorwho.documents.azure.com:443/",
  "Masterkey" -> "YOUR-KEY-HERE",
  "Database" -> "DepartureDelays",
  "Collection" -> "flights_pcoll",
  "query_custom" -> "SELECT c.date, c.delay, c.distance, c.origin, c.destination FROM c WHERE c.origin =
'SEA'" // Optional
))

// Connect via azure-cosmosdb-spark to create Spark DataFrame
val flights = spark.read.cosmosDB(readConfig)
flights.count()
```

Batch writes to Cosmos DB

The following snippet shows how to write a data frame to Cosmos DB in PySpark.

```
# Write configuration
writeConfig = {
    "Endpoint": "https://doctorwho.documents.azure.com:443/",
    "Masterkey": "YOUR-KEY-HERE",
    "Database": "DepartureDelays",
    "Collection": "flights_fromsea",
    "Upsert": "true"
}

# Write to Cosmos DB from the flights DataFrame
flights.write.mode("overwrite").format("com.microsoft.azure.cosmosdb.spark").options(
    **writeConfig).save()
```

And the same code snippet in Scala:

```
// Write configuration

val writeConfig = Config(Map(
  "Endpoint" -> "https://doctorwho.documents.azure.com:443/",
  "Masterkey" -> "YOUR-KEY-HERE",
  "Database" -> "DepartureDelays",
  "Collection" -> "flights_fromsea",
  "Upsert" -> "true"
))

// Write to Cosmos DB from the flights DataFrame
import org.apache.spark.sql.SaveMode
flights.write.mode(SaveMode.Overwrite).cosmosDB(writeConfig)
```

Streaming reads from Cosmos DB

The following snippet shows how to connect to and read from Azure Cosmos DB Change Feed.

```
# Read Configuration
readConfig = {
    "Endpoint": "https://doctorwho.documents.azure.com:443/",
    "Masterkey": "YOUR-KEY-HERE",
    "Database": "DepartureDelays",
    "Collection": "flights_pcoll",
    "ReadChangeFeed": "true",
    "ChangeFeedQueryName": "Departure-Delays",
    "ChangeFeedStartFromTheBeginning": "false",
    "InferStreamSchema": "true",
    "ChangeFeedCheckpointLocation": "dbfs:/Departure-Delays"
}

# Open a read stream to the Cosmos DB Change Feed via azure-cosmosdb-spark to create Spark DataFrame
changes = (spark
           .readStream
           .format("com.microsoft.azure.cosmosdb.spark.streaming.CosmosDBSourceProvider")
           .options(**readConfig)
           .load())
```

And the same code snippet in Scala:

```
// Import Necessary Libraries
import com.microsoft.azure.cosmosdb.spark.schema._
import com.microsoft.azure.cosmosdb.spark._
import com.microsoft.azure.cosmosdb.spark.config.Config

// Read Configuration
val readConfig = Config(Map(
  "Endpoint" -> "https://doctorwho.documents.azure.com:443/",
  "Masterkey" -> "YOUR-KEY-HERE",
  "Database" -> "DepartureDelays",
  "Collection" -> "flights_pcoll",
  "ReadChangeFeed" -> "true",
  "ChangeFeedQueryName" -> "Departure-Delays",
  "ChangeFeedStartFromTheBeginning" -> "false",
  "InferStreamSchema" -> "true",
  "ChangeFeedCheckpointLocation" -> "dbfs:/Departure-Delays"
))

// Open a read stream to the Cosmos DB Change Feed via azure-cosmosdb-spark to create Spark DataFrame
val df = spark.readStream.format(classOf[CosmosDBSourceProvider].getName).options(readConfig).load()
```

Streaming writes to Cosmos DB

The following snippet shows how to write a data frame to Cosmos DB in PySpark.

```
# Write configuration
writeConfig = {
    "Endpoint": "https://doctorwho.documents.azure.com:443/",
    "Masterkey": "YOUR-KEY-HERE",
    "Database": "DepartureDelays",
    "Collection": "flights_fromsea",
    "Upsert": "true",
    "WritingBatchSize": "500",
    "CheckpointLocation": "/checkpointlocation_write1"
}

# Write to Cosmos DB from the flights DataFrame
changeFeed = (changes
              .writeStream
              .format("com.microsoft.azure.cosmosdb.spark.streaming.CosmosDBSinkProvider")
              .outputMode("append")
              .options(**writeconfig)
              .start())
```

And the same code snippet in Scala:

```
// Write configuration

val writeConfig = Config(Map(
  "Endpoint" -> "https://doctorwho.documents.azure.com:443/",
  "Masterkey" -> "YOUR-KEY-HERE",
  "Database" -> "DepartureDelays",
  "Collection" -> "flights_fromsea",
  "Upsert" -> "true",
  "WritingBatchSize" -> "500",
  "CheckpointLocation" -> "/checkpointlocation_write1"
))

// Write to Cosmos DB from the flights DataFrame
df
.writeStream
.format(classOf[CosmosDBSinkProvider].getName)
.options(writeConfig)
.start()
```

More more snippets and end to end samples, see Jupyter.

Working with the connector

You can build the connector from source in GitHub, or download the uber jars from Maven in the links below.

SPARK	SCALA	LATEST VERSION
2.4.0	2.11	azure-cosmosdb-spark_lkg_version
2.3.0	2.11	azure-cosmosdb-spark_2.3.0_2.11_1.3.3
2.2.0	2.11	azure-cosmosdb-spark_2.2.0_2.11_1.1.1
2.1.0	2.11	azure-cosmosdb-spark_2.1.0_2.11_1.2.2

Using Databricks notebooks

Create a library using your Databricks workspace by following the guidance in the Azure Databricks Guide > Use the Azure Cosmos DB Spark connector

> **NOTE**
> The **Use the Azure Cosmos DB Spark Connector** page currently is not up-to-date. Instead of downloading the six separate jars into six different libraries, you can download the uber jar from maven at azure-cosmosdb-spark_lkg_version and install this one jar/library.

Using spark-cli

To work with the connector using the spark-cli (that is, `spark-shell`, `pyspark`, `spark-submit`), you can use the `--packages` parameter with the connector's maven coordinates.

```
spark-shell --master yarn --packages "com.microsoft.azure:azure-cosmosdb-spark_2.4.0_2.11:1.4.0"
```

Using Jupyter Notebooks

If you're using Jupyter Notebook within HDInsight, you can use spark-magic `%%configure` cell to specify the connector's maven coordinates.

```
{ "name":"Spark-to-Cosmos_DB_Connector",
  "conf": {
    "spark.jars.packages": "com.microsoft.azure:azure-cosmosdb-spark_2.4.0_2.11:1.4.0",
    "spark.jars.excludes": "org.scala-lang:scala-reflect"
   }
   ...
}
```

> Note, the inclusion of the `spark.jars.excludes` is specific to remove potential conflicts between the connector, Apache Spark, and Livy.

Build the connector

Currently, this connector project uses `maven` so to build without dependencies, you can run:

```
mvn clean package
```

Working with our samples

The Cosmos DB Spark GitHub repository has the following sample notebooks and scripts that you can try.

- **On-Time Flight Performance with Spark and Cosmos DB (Seattle)** ipynb | html: Connect Spark to Cosmos DB using HDInsight Jupyter Notebook service to showcase Spark SQL, GraphFrames, and predicting flight delays using ML pipelines.
- **Twitter Source with Apache Spark and Azure Cosmos DB Change Feed**: ipynb | html
- **Using Apache Spark to query Cosmos DB Graphs**: ipynb | html
- **Connecting Azure Databricks to Azure Cosmos DB** using `azure-cosmosdb-spark`. Linked here is also an Azure Databricks version of the On-Time Flight Performance notebook.
- **Lambda Architecture with Azure Cosmos DB and HDInsight (Apache Spark)**: You can reduce the operational overhead of maintaining big data pipelines using Cosmos DB and Spark.

More Information

We have more information in the `azure-cosmosdb-spark` wiki including:

Use Apache Spark Structured Streaming with Apache Kafka and Azure Cosmos DB

12/4/2020 • 5 minutes to read • Edit Online

Learn how to use Apache Spark Structured Streaming to read data from Apache Kafka on Azure HDInsight, and then store the data into Azure Cosmos DB.

Azure Cosmos DB is a globally distributed, multi-model database. This example uses a SQL API database model. For more information, see the Welcome to Azure Cosmos DB document.

Spark structured streaming is a stream processing engine built on Spark SQL. It allows you to express streaming computations the same as batch computation on static data. For more information on Structured Streaming, see the Structured Streaming Programming Guide at Apache.org.

> **IMPORTANT**
>
> This example used Spark 2.2 on HDInsight 3.6.
>
> The steps in this document create an Azure resource group that contains both a Spark on HDInsight and a Kafka on HDInsight cluster. These clusters are both located within an Azure Virtual Network, which allows the Spark cluster to directly communicate with the Kafka cluster.
>
> When you are done with the steps in this document, remember to delete the clusters to avoid excess charges.

Create the clusters

Apache Kafka on HDInsight doesn't provide access to the Kafka brokers over the public internet. Anything that talks to Kafka must be in the same Azure virtual network as the nodes in the Kafka cluster. For this example, both the Kafka and Spark clusters are located in an Azure virtual network. The following diagram shows how communication flows between the clusters:

> **NOTE**
>
> The Kafka service is limited to communication within the virtual network. Other services on the cluster, such as SSH and Ambari, can be accessed over the internet. For more information on the public ports available with HDInsight, see Ports and URIs used by HDInsight.

While you can create an Azure virtual network, Kafka, and Spark clusters manually, it's easier to use an Azure Resource Manager template. Use the following steps to deploy an Azure virtual network, Kafka, and Spark clusters to your Azure subscription.

1. Use the following button to sign in to Azure and open the template in the Azure portal.

   Deploy to Azure

   The Azure Resource Manager template is located in the GitHub repository for this project (https://github.com/Azure-Samples/hdinsight-spark-scala-kafka-cosmosdb).

   This template creates the following resources:

   - A Kafka on HDInsight 3.6 cluster.
   - A Spark on HDInsight 3.6 cluster.
   - An Azure Virtual Network, which contains the HDInsight clusters. The virtual network created by the template uses the 10.0.0.0/16 address space.
   - An Azure Cosmos DB SQL API database.

   > **IMPORTANT**
   > The structured streaming notebook used in this example requires Spark on HDInsight 3.6. If you use an earlier version of Spark on HDInsight, you receive errors when using the notebook.

2. Use the following information to populate the entries on the **Custom deployment** section:

PROPERTY	VALUE
Subscription	Select your Azure subscription.
Resource group	Create a group or select an existing one. This group contains the HDInsight cluster.
Cosmos DB Account Name	This value is used as the name for the Cosmos DB account. The name can only contain lowercase letters, numbers, and the hyphen (-) character. It must be between 3-31 characters in length.
Base Cluster Name	This value is used as the base name for the Spark and Kafka clusters. For example, entering **myhdi** creates a Spark cluster named **spark-myhdi** and a Kafka cluster named **kafka-myhdi**.
Cluster Version	The HDInsight cluster version. This example is tested with HDInsight 3.6, and may not work with other cluster types.
Cluster Login User Name	The admin user name for the Spark and Kafka clusters.
Cluster Login Password	The admin user password for the Spark and Kafka clusters.
Ssh User Name	The SSH user to create for the Spark and Kafka clusters.
Ssh Password	The password for the SSH user for the Spark and Kafka clusters.

3. Read the **Terms and Conditions**, and then select **I agree to the terms and conditions stated above**.

4. Finally, select **Purchase**. It may take up to 45 minutes to create the clusters, virtual network, and Cosmos DB account.

Create the Cosmos DB database and collection

The project used in this document stores data in Cosmos DB. Before running the code, you must first create a *database* and *collection* in your Cosmos DB instance. You must also retrieve the document endpoint and the *key* used to authenticate requests to Cosmos DB.

One way to do this is to use the Azure CLI. The following script will create a database named `kafkadata` and a collection named `kafkacollection`. It then returns the primary key.

```
#!/bin/bash

# Replace 'myresourcegroup' with the name of your resource group
resourceGroupName='myresourcegroup'
# Replace 'mycosmosaccount' with the name of your Cosmos DB account name
name='mycosmosaccount'

# WARNING: If you change the databaseName or collectionName
#          then you must update the values in the Jupyter notebook
databaseName='kafkadata'
collectionName='kafkacollection'

# Create the database
az cosmosdb sql database create --account-name $name --name $databaseName --resource-group $resourceGroupName

# Create the collection
az cosmosdb sql container create --account-name $name --database-name $databaseName --name $collectionName --
partition-key-path "/my/path" --resource-group $resourceGroupName

# Get the endpoint
az cosmosdb show --name $name --resource-group $resourceGroupName --query documentEndpoint

# Get the primary key
az cosmosdb keys list --name $name --resource-group $resourceGroupName --type keys
```

The document endpoint and primary key information is similar to the following text:

```
# endpoint
"https://mycosmosaccount.documents.azure.com:443/"
# key
"YqPXw3RP7TsJoBF5imkYR0QNA02IrreNAlkrUMkL8EW94YHs41bktBhIgWq4pqj6HCGYijQKMRkCTsSaKUO2pw=="
```

> **IMPORTANT**
>
> Save the endpoint and key values, as they are needed in the Jupyter Notebooks.

Get the notebooks

The code for the example described in this document is available at https://github.com/Azure-Samples/hdinsight-spark-scala-kafka-cosmosdb.

Upload the notebooks

Use the following steps to upload the notebooks from the project to your Spark on HDInsight cluster:

1. In your web browser, connect to the Jupyter notebook on your Spark cluster. In the following URL, replace `CLUSTERNAME` with the name of your **Spark** cluster:

   ```
   https://CLUSTERNAME.azurehdinsight.net/jupyter
   ```

   When prompted, enter the cluster login (admin) and password used when you created the cluster.

2. From the upper right side of the page, use the **Upload** button to upload the **Stream-taxi-data-to-kafka.ipynb** file to the cluster. Select **Open** to start the upload.

3. Find the **Stream-taxi-data-to-kafka.ipynb** entry in the list of notebooks, and select **Upload** button beside it.

4. Repeat steps 1-3 to load the **Stream-data-from-Kafka-to-Cosmos-DB.ipynb** notebook.

Load taxi data into Kafka

Once the files have been uploaded, select the **Stream-taxi-data-to-kafka.ipynb** entry to open the notebook. Follow the steps in the notebook to load data into Kafka.

Process taxi data using Spark Structured Streaming

From the Jupyter Notebook home page, select the **Stream-data-from-Kafka-to-Cosmos-DB.ipynb** entry. Follow the steps in the notebook to stream data from Kafka and into Azure Cosmos DB using Spark Structured Streaming.

Next steps

Now that you've learned how to use Apache Spark Structured Streaming, see the following documents to learn more about working with Apache Spark, Apache Kafka, and Azure Cosmos DB:

- How to use Apache Spark streaming (DStream) with Apache Kafka.
- Start with Jupyter Notebook and Apache Spark on HDInsight
- Welcome to Azure Cosmos DB

Migrate data to Azure Cosmos DB SQL API account using Striim

12/4/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

The Striim image in the Azure marketplace offers continuous real-time data movement from data warehouses and databases to Azure. While moving the data, you can perform in-line denormalization, data transformation, enable real-time analytics, and data reporting scenarios. It's easy to get started with Striim to continuously move enterprise data to Azure Cosmos DB SQL API. Azure provides a marketplace offering that makes it easy to deploy Striim and migrate data to Azure Cosmos DB.

This article shows how to use Striim to migrate data from an **Oracle database** to an **Azure Cosmos DB SQL API account**.

Prerequisites

- If you don't have an Azure subscription, create a free account before you begin.
- An Oracle database running on-premises with some data in it.

Deploy the Striim marketplace solution

1. Sign into the Azure portal.
2. Select **Create a resource** and search for **Striim** in the Azure marketplace. Select the first option and **Create**.

3. Next, enter the configuration properties of the Striim instance. The Striim environment is deployed in a virtual machine. From the **Basics** pane, enter the **VM user name**, **VM password** (this password is used to SSH into the VM). Select your **Subscription**, **Resource Group**, and **Location details** where you'd like to

deploy Striim. Once complete, select **OK**.

4. In the **Striim Cluster settings** pane, choose the type of Striim deployment and the virtual machine size.

SETTING	VALUE	DESCRIPTION
Striim deployment type	Standalone	Striim can run in a **Standalone** or **Cluster** deployment types. Standalone mode will deploy the Striim server on a single virtual machine and you can select the size of the VMs depending on your data volume. Cluster mode will deploy the Striim server on two or more VMs with the selected size. Cluster environments with more than 2 nodes offer automatic high availability and failover. In this tutorial, you can select Standalone option. Use the default "Standard_F4s" size VM.
Name of the Striim cluster	<Striim_cluster_Name>	Name of the Striim cluster.
Striim cluster password	<Striim_cluster_password>	Password for the cluster.

After you fill the form, select **OK** to continue.

5. In the **Striim access settings** pane, configure the **Public IP address** (choose the default values), **Domain name for Striim**, **Admin password** that you'd like to use to login to the Striim UI. Configure a VNET and Subnet (choose the default values). After filling in the details, select **OK** to continue.

6. Azure will validate the deployment and make sure everything looks good; validation takes few minutes to complete. After the validation is completed, select **OK**.

7. Finally, review the terms of use and select **Create** to create your Striim instance.

Configure the source database

In this section, you configure the Oracle database as the source for data movement. You'll need the Oracle JDBC driver to connect to Oracle. To read changes from your source Oracle database, you can either use the LogMiner or the XStream APIs. The Oracle JDBC driver must be present in Striim's Java classpath to read, write, or persist data from Oracle database.

Download the ojdbc8.jar driver onto your local machine. You will install it in the Striim cluster later.

Configure the target database

In this section, you will configure the Azure Cosmos DB SQL API account as the target for data movement.

1. Create an Azure Cosmos DB SQL API account using the Azure portal.

2. Navigate to the **Data Explorer** pane in your Azure Cosmos account. Select **New Container** to create a new container. Assume that you are migrating *products* and *orders* data from Oracle database to Azure Cosmos DB. Create a new database named **StriimDemo** with a container named **Orders**. Provision the container with **1000 RUs** (this example uses 1000 RUs, but you should use the throughput estimated for your workload), and **/ORDER_ID** as the partition key. These values will differ depending on your source data.

Configure Oracle to Azure Cosmos DB data flow

1. Now, let's get back to Striim. Before interacting with Striim, install the Oracle JDBC driver that you downloaded earlier.

2. Navigate to the Striim instance that you deployed in the Azure portal. Select the **Connect** button in the upper menu bar and from the **SSH** tab, copy the URL in **Login using VM local account** field.

3. Open a new terminal window and run the SSH command you copied from the Azure portal. This article uses terminal in a MacOS, you can follow the similar instructions using PuTTY or a different SSH client on a Windows machine. When prompted, type **yes** to continue and enter the **password** you have set for the virtual machine in the previous step.

```
Striim — striimdemo@striimdemo-masternode:~ — ssh striimdemo@striimdemo.westus.cloud
Striim-Edwards-MacBook-Pro:Striim edwardbell$ ssh striimdemo@striimdemo.westus.cloudapp.azure.com
Password:
Last login: Tue Jul 16 21:04:40 2019 from 208.89.164.26
[striimdemo@striimdemo-masternode ~]$
```

4. Now, open a new terminal tab to copy the **ojdbc8.jar** file you downloaded previously. Use the following SCP command to copy the jar file from your local machine to the tmp folder of the Striim instance running in Azure:

```
cd <Directory_path_where_the_Jar_file_exists>
scp ojdbc8.jar striimdemo@striimdemo.westus.cloudapp.azure.com:/tmp
```

```
Jars — ssh ◂ scp ojdbc8.jar striimdemo@striimdemo.westus.cloudapp.azure.com:/tmp — 134×27
...e:~ — ssh striimdemo@striimdemo.westus.cloudapp.azure.com ...striimdemo@striimdemo.westus.cloudapp.azure.com:/tmp
Last login: Tue Jul 16 14:03:40 on ttys001
Striim-Edwards-MacBook-Pro:Striim edwardbell$ cd /Users/edwardbell/Desktop/Jars
Striim-Edwards-MacBook-Pro:Jars edwardbell$ scp ojdbc8.jar striimdemo@striimdemo.westus.cloudapp.azure.com:/tmp
Password:
ojdbc8.jar                                                    82% 3360KB   2.3MB/s   00:00 ETA
```

5. Next, navigate back to the window where you did SSH to the Striim instance and Login as sudo. Move the **ojdbc8.jar** file from the **/tmp** directory into the **lib** directory of your Striim instance with the following commands:

```
sudo su
cd /tmp
mv ojdbc8.jar /opt/striim/lib
chmod +x ojdbc8.jar
```

```
Striim — root@striimdemo-masternode:/opt/striim/lib — ssh striimdemo@striimdemo.westus.cloudapp.azure.com — 13...
.../lib — ssh striimdemo@striimdemo.westus.cloudapp.azure.com ~/Desktop/Jars — -bash
Striim-Edwards-MacBook-Pro:Striim edwardbell$ ssh striimdemo@striimdemo.westus.cloudapp.azure.com
Password:
Last login: Tue Jul 16 21:05:02 2019 from 208.89.164.26
[striimdemo@striimdemo-masternode ~]$ sudo su
[sudo] password for striimdemo:
[root@striimdemo-masternode striimdemo]# cd /tmp
[root@striimdemo-masternode tmp]# ls
hsperfdata_root  hsperfdata_striim  jna--891986052  ojdbc8.jar
[root@striimdemo-masternode tmp]# mv ojdbc8.jar /opt/striim/lib
[root@striimdemo-masternode tmp]# cd /opt/striim/lib
[root@striimdemo-masternode lib]# chmod +x ojdbc8.jar
```

6. From the same terminal window, restart the Striim server by executing the following commands:

```
Systemctl stop striim-node
Systemctl stop striim-dbms
Systemctl start striim-dbms
Systemctl start striim-node
```

7. Striim will take a minute to start up. If you'd like to see the status, run the following command:

```
tail -f /opt/striim/logs/striim-node.log
```

8. Now, navigate back to Azure and copy the Public IP address of your Striim VM.

9. To navigate to the Striim's Web UI, open a new tab in a browser and copy the public IP followed by: 9080. Sign in by using the **admin** username, along with the admin password you specified in the Azure portal.

10. Now you'll arrive at Striim's home page. There are three different panes – **Dashboards**, **Apps**, and **SourcePreview**. The Dashboards pane allows you to move data in real time and visualize it. The Apps pane contains your streaming data pipelines, or data flows. On the right hand of the page is SourcePreview where you can preview your data before moving it.

11. Select the **Apps** pane, we'll focus on this pane for now. There are a variety of sample apps that you can use to learn about Striim, however in this article you will create our own. Select the **Add App** button in the top

right-hand corner.

12. There are a few different ways to create Striim applications. Select **Start with Template** to start with an existing template.

13. In the **Search templates** field, type "Cosmos" and select **Target: Azure Cosmos DB** and then select **Oracle CDC to Azure Cosmos DB**.

14. In the next page, name your application. You can provide a name such as **oraToCosmosDB** and then select

Save.

15. Next, enter the source configuration of your source Oracle instance. Enter a value for the **Source Name**. The source name is just a naming convention for the Striim application, you can use something like **src_onPremOracle**. Enter values for rest of the source parameters **URL**, **Username**, **Password**, choose **LogMiner** as the reader to read data from Oracle. Select **Next** to continue.

16. Striim will check your environment and make sure that it can connect to your source Oracle instance, have the right privileges, and that CDC was configured properly. Once all the values are validated, select **Next**.

17. Select the tables from Oracle database that you'd like to migrate. For example, let's choose the Orders table and select **Next**.

18. After selecting the source table, you can do more complicated operations such as mapping and filtering. In this case, you will just create a replica of your source table in Azure Cosmos DB. So, select **Next** to configure the target

19. Now, let's configure the target:

    - **Target Name** - Provide a friendly name for the target.
    - **Input From** - From the dropdown list, select the input stream from the one you created in the source Oracle configuration.
    - **Collections**- Enter the target Azure Cosmos DB configuration properties. The collections syntax is **SourceSchema.SourceTable, TargetDatabase.TargetContainer**. In this example, the value would be "SYSTEM.ORDERS, StriimDemo.Orders".
    - **AccessKey** - The PrimaryKey of your Azure Cosmos account.
    - **ServiceEndpoint** – The URI of your Azure Cosmos account, they can be found under the **Keys** section of the Azure portal.

    Select **Save** and **Next**.

20. Next, you'll arrive at the flow designer, where you can drag and drop out of the box connectors to create your streaming applications. You will not make any modifications to the flow at this point. so go ahead and deploy the application by selecting the **Deploy App** button.

21. In the deployment window, you can specify if you want to run certain parts of your application on specific parts of your deployment topology. Since we're running in a simple deployment topology through Azure, we'll use the default option.

22. After deploying, you can preview the stream to see data flowing through. Select the **wave** icon and the eyeball next to it. Select the **Deployed** button in the top menu bar, and select **Start App**.

23. By using a **CDC(Change Data Capture)** reader, Striim will pick up only new changes on the database. If you have data flowing through your source tables, you'll see it. However, since this is a demo table, the source isn't connected to any application. If you use a sample data generator, you can insert a chain of events into your Oracle database.

24. You'll see data flowing through the Striim platform. Striim picks up all the metadata associated with your table as well, which is helpful to monitor the data and make sure that the data lands on the right target.

25. Finally, let's sign into Azure and navigate to your Azure Cosmos account. Refresh the Data Explorer, and you can see that data has arrived.

By using the Striim solution in Azure, you can continuously migrate data to Azure Cosmos DB from various sources such as Oracle, Cassandra, MongoDB, and various others to Azure Cosmos DB. To learn more please visit the Striim website, download a free 30-day trial of Striim, and for any issues when setting up the migration path with Striim, file a support request.

Next steps

- If you are migrating data to Azure Cosmos DB SQL API, see how to migrate data to Cassandra API account using Striim
- Monitor and debug your data with Azure Cosmos DB metrics

Migrate one-to-few relational data into Azure Cosmos DB SQL API account

11/2/2020 • 8 minutes to read • Edit Online

APPLIES TO: SQL API

In order to migrate from a relational database to Azure Cosmos DB SQL API, it can be necessary to make changes to the data model for optimization.

One common transformation is denormalizing data by embedding related subitems within one JSON document. Here we look at a few options for this using Azure Data Factory or Azure Databricks. For general guidance on data modeling for Cosmos DB, please review Data modeling in Azure Cosmos DB.

Example Scenario

Assume we have the following two tables in our SQL database, Orders and OrderDetails.

We want to combine this one-to-few relationship into one JSON document during migration. To do this, we can create a T-SQL query using "FOR JSON" as below:

```
SELECT
  o.OrderID,
  o.OrderDate,
  o.FirstName,
  o.LastName,
  o.Address,
  o.City,
  o.State,
  o.PostalCode,
  o.Country,
  o.Phone,
  o.Total,
  (select OrderDetailId, ProductId, UnitPrice, Quantity from OrderDetails od where od.OrderId = o.OrderId for
json auto) as OrderDetails
FROM Orders o;
```

The results of this query would look as below:

Ideally, you want to use a single Azure Data Factory (ADF) copy activity to query SQL data as the source and write the output directly to Azure Cosmos DB sink as proper JSON objects. Currently, it is not possible to perform the needed JSON transformation in one copy activity. If we try to copy the results of the above query into an Azure Cosmos DB SQL API container, we will see the OrderDetails field as a string property of our document, instead of the expected JSON array.

We can work around this current limitation in one of the following ways:

- **Use Azure Data Factory with two copy activities**:
  1. Get JSON-formatted data from SQL to a text file in an intermediary blob storage location, and
  2. Load data from the JSON text file to a container in Azure Cosmos DB.
- **Use Azure Databricks to read from SQL and write to Azure Cosmos DB** - we will present two options here.

Let's look at these approaches in more detail:

Azure Data Factory

Although we cannot embed OrderDetails as a JSON-array in the destination Cosmos DB document, we can work around the issue by using two separate Copy Activities.

Copy Activity #1: SqlJsonToBlobText

For the source data, we use a SQL query to get the result set as a single column with one JSON object (representing the Order) per row using the SQL Server OPENJSON and FOR JSON PATH capabilities:

```
SELECT [value] FROM OPENJSON(
  (SELECT
    id = o.OrderID,
    o.OrderDate,
    o.FirstName,
    o.LastName,
    o.Address,
    o.City,
    o.State,
    o.PostalCode,
    o.Country,
    o.Phone,
    o.Total,
    (select OrderDetailId, ProductId, UnitPrice, Quantity from OrderDetails od where od.OrderId = o.OrderId for
json auto) as OrderDetails
   FROM Orders o FOR JSON PATH)
)
```

For the sink of the SqlJsonToBlobText copy activity, we choose "Delimited Text" and point it to a specific folder in Azure Blob Storage with a dynamically generated unique file name (for example, '@concat(pipeline().RunId,'.json'). Since our text file is not really "delimited" and we do not want it to be parsed into separate columns using commas and want to preserve the double-quotes ("), we set "Column delimiter" to a Tab ("\t") - or another character not occurring in the data - and "Quote character" to "No quote character".

Copy Activity #2: BlobJsonToCosmos
